The Anterior Ulnar Recurrent (a. recurrentes ulnaris anterior) (Fig. 414) arises immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies twigs to those muscles, and, in front, of the inner condyle anastomoses with the anastomotica magna and inferior profunda.

The Posterior Ulnar Recurrent (a. recurrentes ulnaris posterior) (Figs. 414 and 415) is much larger, and arises somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and intersosseous recurrent arteries.

The Intersosseous Artery (a. interossea communis) (Fig. 414) is a short trunk about half an inch in length, and of considerable size, which arises immediately, below the tuberosity of the radius, and, passing backward to the upper border of the intersosseous membrane, divides into two branches, the anterior and posterior intersosseous.

The Anterior Interosseous (a. interossea volaris) (Fig. 414) passes down the forearm on the anterior surface of the intersosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the intersosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch, anterior communicating artery, descends beneath the muscle to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the intersosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 415). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives
off a long, slender branch, the **median artery** or artery comes **nervi mediana** (*a. mediana*), which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged, and accompanies the nerve into the palm of the hand.

The **Posterior Interosseous Artery** (*a. interossea dorsalis*) (Figs. 414 and 415) passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the **interosseous recurrent** branch.

The **interosseous recurrent artery** (*a. interossea recurrens*) (Fig. 415) is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **Muscular Branches** (*rami musculares*) are distributed to the muscles along the ulnar side of the forearm.

The **Anterior Carpal** (*ramus carpeus volaris*) (Fig. 414) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.

The **Posterior Carpal** (*ramus carpeus dorsalis*) (Fig. 415) arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the extensor
tendons, anastomosing with a corresponding branch of the radial artery, and forming the posterior carpal arch (rete carpi dorsale) (Fig. 415). Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the metacarpal arteries, and supplies the ulnar side of the dorsal surface of the little finger.

The Deep or Communicating Branch to the Deep Palmar Arch (ramus volaris profundus) (Fig. 414) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digiti, near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The continuation of the trunk of the ulnar artery in the hand forms the greater part of the superficial palmar arch.

The Superficial Palmar Arch (arcus volaris superficialis) (Fig. 413) is formed by the ulnar artery in the hand, and is completed on the outer side by this vessel anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by the ulnar anastomosing with the superficialis volae or the princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity forward, to the space between the ball of the thumb and the index finger, where the above-mentioned anastomosis takes place.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, the Flexor brevis of the little finger, the tendons of the superficial flexor of the fingers, and the divisions of the median and ulnar nerves.

Plan of the Relations of the Superficial Palmar Arch.

\]

Branches.—The branches of the Superficial Palmar Arch are the Digital.

The Digital Branches (aa. digitales volares communnes) (Fig. 413), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.
Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger. The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, by enlarging the wound if necessary, to secure the vessel and tie it; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of hemostatic forceps may be applied and left on for twenty-four or forty-eight hours. Wounds of the deep arch are not so easily dealt with. It may be possible to secure the vessel by ligature or by forcible pressure forceps, which may be left on; or, failing in this, the wound may be carefully plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days.

In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligate one of the arteries of the forearm alone, and indeed simultaneous ligation of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, if unable to ligate the divided ends of the arch, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery.

**ARteries of the Trunk.**

**The Descending Aorta (Figs. 416, 417).**

The descending aorta is divided into two portions, the thoracic and abdominal, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta (Aorta Thoracalis) (Fig. 416).

The thoracic aorta commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last dorsal vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the spinal column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

**Relations.**—It is in relation, in front, from above downward, with the root of the left lung, the pericardium, the esophagus, and the Diaphragm: behind, with the vertebral column and the vena azygos minor; on the right side, with the vena azygos major and thoracic duct; on the left side, with the left pleura and lung. The esophagus, with its accompanying nerves, lies on the right side of the aorta above; but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

- Esophagus (below).

**Behind.**
- Vertebral column.
- Superior and inferior azygos minor veins.
The aorta is occasionally found to be obliterated at a particular spot—viz., at the junction of the arch with the thoracic aorta just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the Pathological Transactions, vols. vii. and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels: “The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals.” In the second case also (vol. x. p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that “the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics.”

Surgical Anatomy.—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebrae, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscesses connected with diseased bone, or it may displace the oesophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the oesophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hemorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and, lastly, it may open into the posterior mediastinum.

Branches.—Branches of the thoracic aorta supply the thoracic viscera. They are known as rami viscerales. The rami viscerales are the bronchial, cesophageal, pericardial, and mediastinal arteries. Other branches of the thoracic aorta supply the walls of the chest. They are known as rami parietales or intercostal arteries.

The Bronchial Arteries (aa. bronchiales) are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing along the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the oesophagus.

The Cesophageal Arteries (aa. cesophageae), usually four or five in number, arise from the front of the aorta, and pass obliquely downward to the oesophagus, forming a chain of anastomoses along that tube, anastomosing with the cesophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The Pericardiac (rami pericardiae) are a few small vessels, irregular in their origin, distributed to the pericardium.

The Posterior Mediastinal Arteries (rami mediastinales) are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.
The lower mediastinal branches are known as the superior phrenic arteries (aa. phrenicæ superiores), and are distributed to the posterior portion of the Diaphragm.

The Intercostal Arteries (aa. intercostales) (Fig. 416) arise from the back of the aorta. The aortic intercostals are usually nine in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The second space usually receives a considerable branch from the first aortic intercostal, which joins with the branch from the superior intercostal of the subclavian. The branch which runs along the lower border of the last rib is named the subcostal artery. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine: they pass outward, across the bodies of the vertebrae, to the intercostal spaces, being covered by the pleura, the oesophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left, passing outward, are crossed by the sympathetic; the upper two are also crossed by the superior intercostal vein, the lower by the azygos minor veins. In each intercostal space the artery passes outward, the External intercostal muscle being behind, the pleura and a thin fascia being in front. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above it, is continued forward in the groove on its lower border and anastomoses with the anterior intercostal branches of the internal mammary. The first aortic intercostal anastomoses with the superior intercostal branch of the subclavian, and the last three intercostals pass between the abdominal muscles, inosculating with the epigastric in front and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the subcostal, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

Branches.—Each intercostal artery gives off numerous muscular branches (rami musculares).

Lateral Cutaneous Branches (rami cutanei laterales) come off from each intercostal and take a similar course to that of the lateral cutaneous branch of the intercostal nerve. These arteries are distributed to the walls of the chest and to the mammary gland (rami mammarii laterales).

Small branches pass to the mammary gland through the fourth, fifth, and sixth interspaces (rami mammarii medialis), and to the skin to the inner side of the nipple (rami cutanei arteriores).

The portion of the artery considered here as the prolongation of the main trunk is called by Spalteholz and others the anterior branch (ramus anterior).

The Posterior or Dorsal Branch (ramus posterior) of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into an external branch (ramus cutaneus lateralis), and an internal branch (ramus cutaneus medialis), which are distributed to the muscles and integument of the back. Muscular branches (rami musculares) are given off by the dorsal branch soon after its origin. A spinal branch (ramus spinalis) comes off from the dorsal branch of the intercostal. It traverses the vertebral arches and enters the spinal canal through the intervertebral foramen, is distributed to the spinal cord and its membranes; and to the bodies of the vertebra in the same manner as the lateral spinal branches from the vertebral. It gives off three branches, the neural, which accompanies the spinal nerve-roots, and is distributed to the membranes of the spinal cord. The post-central branch divides into ascending and descending branches, which, anastomosing with similar branches above and below, form a series of vertical arches in the back of the bodies of the vertebra. The prelaminar branch is distributed to "the posterior wall of the spinal canal."

The Collateral Intercostal Branch comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary or its branch, the musculo-phrenic.

The two lower intercostals on each side have not constant collateral branches. Even when present they are of small size and end in the wall of the abdomen. Each collateral intercostal branch gives off muscular branches.

Surgical Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The Abdominal Aorta (Aorta Abdominalis) (Fig. 417).

The abdominal aorta commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last dorsal vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line, where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebra, the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

1 Cunningham's Text-book of Anatomy.
2 Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less, to the left, and in 2 was slightly to the right" (System of Surgery, edited by T. Holmes, 2d ed., vol. v, p. 652).—Ed. of 15th English edition.
Relations.—It is covered, in front, by the lesser omentum and stomach, behind which are the branches of the coeliac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. Behind, it is separated from the lumbar vertebrae and intervening disks by the anterior common ligament and left lumbar veins. On the right side it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the left side, with the sympathetic nerve and left semilunar ganglion.
PLAN OF THE RELATIONS OF THE ABDOMINAL AORTA.

Vertebral column.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—ANEURISMS OF THE ABDOMINAL AORTA near the celiac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebrae, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart’s ligament; hemorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the celiac axis it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and is accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it seldom extends backward so as to affect the spine.

The abdominal aorta has been tied 15 times, and although none of the patients permanently recovered, still, as Prof. Keen’s lived 48 days, the possibility of the re-establishment of the circulation is proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, in 1817, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mam-
mary and the deep epigastric; by the free communication between the superior and inferior mesenteries if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

During an amputation at the hip the circulation through the abdominal aorta may be commanded by an assistant, who throws the entire weight of his body upon his rigidly extended forearm, the fist of which lies directly upon the patient's aorta (Macewen's method). The abdominal tourniquet is no longer used, as modern methods enable the surgeon to do a practically bloodless hip-joint amputation (Wyeth's method, Senn's method, McBurney's method).

**Branches** (Fig. 417).—The branches of the abdominal aorta are—the

- Phrenic
- Superior Mesenteric. Ovarian in female.
- Gastric. Suprarenal. Inferior Mesenteric. Lumbar.
- Coeliac Axis Splenic. Spermatic in male.
- Hepatic. Sacra Media.
- Superior Mesenteric.
- Renal.
- Splenic.

**Branches.**—The branches of the abdominal aorta may be divided into two sets: 1. Those supplying the *viscera* (rami viscerales). 2. Those distributed to the walls of the *abdomen* (rami parietales).

**Visceral Branches.**

- Coeliac Axis Gastric.
- Superior Mesenteric. Hepatic.
- Splenic. Inferior Phrenic.
- Inferior Mesenteric. Lumbar.
- Suprarenal. Sacra Media.
- Renal.
- Spermatic or Ovarian.

To expose the coeliac axis raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

**The Coeliac Axis or Artery (a. coeliaca)** (Figs. 417, 418, and 419).—The coeliac axis is a short thick trunk, about half an inch in length, which arises from the aorta, close to the margin of the opening in the Diaphragm, behind the posterior parietal peritoneum, above the pancreas, and below the twelfth dorsal vertebra, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the *gastric*, *hepatic*, and *splenic*, occasionally giving off one of the phrenic arteries.

**Relations.**—It is covered by the lesser omentum. On the right side it is in relation with the right semilunar ganglion and the lobus Spigelii; on the left side, with the left semilunar ganglion and cardiac end of the stomach. Below, it rests upon the upper border of the pancreas.

**The Gastric or Coronary Artery (a. gastrica sinistra)** (Figs. 418 and 419), the smallest of the three branches of the coeliac axis, passes upward and to the left side, behind the peritoneum of the lesser peritoneal cavity, raising this portion of the peritoneum into a fold, known as the left or secondary pancreatico-gastric fold. It continues this course until it nearly reaches the lesser curvature of the stomach just below the cardia. It then turns to the front and curves forward to the cardiac orifice of the stomach, distributing branches to the oesophagus which anastomose with the aortic oesophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along and upon the lesser curvature of the stomach and beneath the peritoneum to the pylorus, lying in its course between the layers of the lesser omentum, and sometimes dividing into two vessels, which run along each side
of the lesser curvature. One vascular arch gives branches to the anterior wall of the stomach and the other to the posterior wall (Fig. 886), and both give them to the lesser omentum or the single artery gives branches to both surfaces of the organ and to the lesser omentum: at its termination it anastomoses with the pyloric branch or the two pyloric branches of the hepatic. It gives off gastric branches to both the anterior and posterior surfaces of the stomach, branches to the lesser omentum, a small hepatic branch, to the left lobe of the liver and oesophageal branches (rami oesophagei) which anastomose with oesophageal branches from the thoracic aorta and the inferior phrenic.

The Hepatic Artery (a. hepatica) (Figs. 418 and 419) in the adult is intermediate in size between the gastric and splenic; in the fetus it is the largest of the three branches of the celiac axis. It is first directed forward and to the right, in the right pancreatico-gastric fold, to the upper margin of the pyloric end of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portae and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portae behind.
Its branches (Figs. 418 and 419) are—the
Pyloric.
  Gastro-duodenalis  \{  Gastro-epiploica Dextra.
  (Pancreatico-duodenalis Superior
Cystic.

The pyloric or superior pyloric branch (a. gastrica dextra) arises from the hepatic, above the pylorus, descends between the layers of the lesser omentum to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and inosculating with the gastric branches of the coronary artery. The vessel often divides into two vascular arches to anastomose with two vascular arches from the gastric.

The gastro-duodenalis (Fig. 419) is a short but large branch, which descends near the pylorus, behind the first portion of the duodenum, and divides at the lower border of this viscus into two branches, the gastro-epiploica dextra and the pancreatico-duodenalis superior. Previous to its division, it gives off two or three small inferior pyloric branches, to the pyloric end of the stomach and pancreas.

The gastro-epiploica dextra runs from right to left along but distinctly below the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the gastro-epiploica sinistra from the splenic artery. This vessel gives off numerous branches,
some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum (rami epiploici).

The pancreatico-duodenalis superior descends between the contiguous margins of the duodenum and pancreas. It supplies the head of the pancreas by means of the rami pancreatica, and the duodenum by means of the rami duodenalis, and anastomoses with the inferior pancreatice-duodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The cystic artery (a. cystica) (Fig. 418), usually a branch of the right hepatic, passes downward and forward along the cystic duct to the gall-bladder, and divides into two branches, one of which ramifies on its free surface beneath the peritoneum, the other between the gall-bladder and the substance of the liver.

The Splenic Artery (a. lienalis) (Figs. 418 and 419), in the adult, is the largest of the three branches of the celiac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the pancreas and great end of the stomach. Its branches are—the

- Pancreatice Parvae.
- Pancreatice Magna.
- Gastric (Vasa Brevia).
- Gastro-epiploica Sinistra.
- Rami Lienalis.

The pancreatic branches (rami pancreaticei) are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the pancreatice magna. The others are called the pancreatice parvae. These vessels anastomose with the pancreatic branches of the pancreatice-duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The gastric branches or vasa brevia (aa. gastrice breves) consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The gastro-epiploica sinistra, the largest branch of the splenic, runs from left to right along but distinctly below the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

The rami lienales leave the splenic artery in the hilum and pass into the spleen.

**Surgical Anatomy.**—The operation of pylorectomy can be made an almost bloodless procedure by tying the gastric, the pyloric, and the right and left gastro-epiploica arteries. "The gastric is doubly tied about one inch below the cardiac orifice at a point where it joins the lesser curvature and is divided between the ligatures. The superior pyloric is doubly tied and divided. The fingers are passed beneath the pylorus, raising the gastro-colic omentum from the transverse mesocolon, and in this way safe ligation behind the pylorus of the right gastro-epiploica artery, or in most cases its parent vessel, the gastro-duodenal, is secured. The left gastro-epiploica is now tied at an appropriate point, and the necessary amount of gastro-colic omentum doubly tied and cut."1

---

The Superior Mesenteric Artery (a. mesenterica superior) (Figs. 417 and 420).
—The superior mesenteric artery supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cecum and the ascending and transverse colon; it is a vessel of large size, arising from the forepart of the aorta about a quarter of an inch below the celiac axis; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and the transverse portion of the duodenum, crosses in front of this portion of the intestine, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches—viz., the ileo-colic. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves.

In order to expose the superior mesenteric artery raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join; the artery will then be exposed just as it issues from beneath the lower border of the pancreas.

Branches.—Its branches are—the

- Inferior Pancreatico-duodenal.
- Vasa Intestini Tenuis.
- Middle Colic.
- Ileo-colic.
- Right Colic.

The Inferior Pancreatico-duodenal (a. pancreaticoduodenalis inferior) is given off from the superior mesenteric, or from its first intestinal branch behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatico-duodenal artery. It distributes branches to the head of the pancreas and to the transverse and descending portions of the duodenum.

The Vasa Intestini Tenuis (aa. intestinales) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum (aa. jejunales) and ileum (aa. ileae). They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with similar branches on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third and a fourth, or even a fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the glands and other structures between the layers of the mesentery. (See the description of the vascular loops in the section upon the Intestines. The form and arrangement of the loops have been studied by Monks, of Boston.)

The Ileo-colic Artery (a. ileocolica) is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior division inosculates with the termination of the superior mesenteric artery, forming with it an arch, from the convexity of which branches proceed to supply the termination of the ileum, the cecum, the vermiform appendix, and the ileo-cecal valve. The superior division inosculates with the colica dextra and supplies the commencement of the colon.

The Right Colic Artery (a. colica dextra) arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum
to the middle of the ascending colon, divides into two branches—a **descending branch**, which inosculates with the ileo-colic, and an **ascending branch**, which anastomoses with the colica media. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The **Middle Colic Artery** (*a. colica media*) arises from the upper part of the concavity of the superior mesenteric, and, passing forward between the layers of the transverse mesocolon, divides into two branches, the one on the right side inosculating with the colica dextra; that on the left side, with the colica sinistra, a branch of the inferior mesenteric. From the arches formed by their inosulation branches are distributed to the transverse colon. The branches of this vessel lie between the two layers of the transverse mesocolon.

**Blood-supply of the Right Iliac Fossa.**—The descending branch of the right colic artery by anastomosing with the ascending branch of the ileo-colic artery forms a vascular loop. The union of the descending branch of the ileo-colic artery with the terminal vessel of the superior mesenteric artery forms another vascular loop. These two loops give off secondary loops, and from the secondary loops come the vessels which supply the appendix, the cecum, and the lower end of the ileum. The branch which goes to the appendix is called the **appendicular artery** (*a. appendicularis*). If there is a distinct meso-appendix the artery passes along its unattached edge. If there is a rudimentary meso-appendix or no meso-appendix the artery
THE ABDOMINAL AORTA

usually lies upon the appendix from base to tip beneath the peritoneal covering. In females the appendix may receive an additional vessel from the ovarian, which vessel lies in the appendiculo-ovarian ligament.

The Inferior Mesenteric Artery (a. mesenterica inferior) (Figs. 417 and 421).—The inferior mesenteric artery supplies the descending colon, the sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the left side of the aorta, between one and two inches above the division of that vessel into the common iliacs. It passes downward to the left iliac fossa, and then descends between the layers of the mesorectum, into the pelvis, under the name of the superior haemorrhoidal artery. It lies at first in close relation with the left side of the aorta, and then passes as the superior haemorrhoidal in front of the left common iliac artery.

In order to expose the inferior mesenteric artery draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front of the aorta.

Branches.—Its branches are—the

Left Colic. Superior Haemorrhoidal.

Sigmoid.
The Left Colic Artery (a. colica sinistra) passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the colica media; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations branches are distributed to the descending colon.

The Sigmoid Arteries (aa. sigmoideae).—As a rule there are two of these vessels, but may be three. They run obliquely downward across the Psoas muscle to the sigmoid flexure of the colon, and divide into branches which supply that part of the intestine, anastomosing above with the left colic, and below with the superior haemorrhoidal artery.

The Superior Haemorrhoidal Artery (a. haemorrhoidalis superior) (Figs. 421 and 424), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesorectum, crossing, in its course, the ureter and left common iliac vessels. Opposite the middle of the sacrum it divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel and run downward, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coat, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle haemorrhoidal arteries which are branches of the internal iliac and with the inferior haemorrhoidal branches of the internal pudic.
mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Before reaching the hilum of the kidney, each artery usually divides into four branches. Two of these vessels enter the anterior portion and two the posterior portion of the kidney. There may be but one renal artery; there may be two, three, four, or five branches. The greater number of the branches generally lie between the renal vein and ureter, the vein being in front of the arteries, the ureter behind. The anterior branches supply three-fourths of the kidney, the posterior supply one-fourth. Each vessel gives off a small branch to the suprarenal capsule (a. suprarenalis inferior) and branches to the ureter, ureteral branches, and to the surrounding cellular tissue and muscles, perirenal branches. Hyrtl, in 1870, pointed out that the renal artery gives off a branch which divides and supplies the dorsal or posterior portion of the kidney and

its pelvis, and a branch which divides and supplies the ventral or anterior portion of the kidney and its pelvis. The two circulations are distinct and do not anastomose even at the periphery. Between these two sets of vessels is a bloodless zone called by Byron Robinson the exsanguinated renal zone of Hyrtl, which does not correspond to the median line, but is "one-half inch dorsal to the lateral longitudinal renal border." The ventral or anterior segment is much the larger. In very rare instances the bloodless zone corresponds to the median line (Kümmel). An incision of the middle third of the kidney exactly at the junction of the two segments does not divide vessels. As the incision approaches either pole there is danger of cutting a branch (Schede). Frequently there is a second renal artery, which is given off from the abdominal aorta either above or below the renal artery proper, the former being the more common position. Instead of entering the kidney at the hilum, an accessory renal artery usually pierces the upper or the lower part of the gland.

The Spermatic Arteries (aa. spermaticæ internæ) (Fig. 417).—The internal spermatic arteries are distributed to the testes. They are two slender vessels of

---

1 Byron Robinson. The Circulation of the Kidney, American Journal of Surgery.
considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter (to which it sends a few branches) and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous and is prolonged as the testicular artery, which accompanies the vas deferens, anastomosing with the artery of the vas deferens and is distributed to the epididymis, the back part of the tunica albuginea, and the substance of the testes. The spermatic artery in the inguinal canal gives off cremasteric branches to supply the Cremaster muscle. In the canal and scrotum the artery lies behind the pampiniform plexus and in front of the vas deferens.

The Ovarian Arteries (aa. ovaricae).—The ovarian arteries (Fig. 425) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two layers of the broad ligament of the uterus, to be distributed to the ovary, ovarian branches. Branches go to the Fallopian tube, tubal branches, the ureter, ureteral branches, and the broad ligament, ligamentous branches. A branch passes on to the side of the uterus and anastomoses with the uterine arteries, uterine branch. Other offsets are continued along the round ligament through the inguinal canal, to the integument of the labium and groin.

At an early period of foetal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries become gradually lengthened.

The Inferior Phrenic Arteries (aa. phrenicae inferiores) (Fig. 417).—The inferior phrenic arteries are two small vessels which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the celiac axis, or by a common trunk, which may spring either from the aorta or from the celiac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon the under surface of the Diaphragm. The left phrenic passes behind the œsophagus and runs forward on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The internal branch runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of the opposite side, and with the musculo-phrenic and comes nervi phrenici branches of the internal mammary. The external branch passes toward the side of the thorax and inosculates with the intercostal arteries. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the œsophagus. Each vessel also sends capsular branches (rami suprarenales superior) to the suprarenal capsule of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

The Lumbar Arteries (aa. lumbales).—The lumbar arteries are analogous to the intercostals. They are usually four in number on each side, and arise from the back part of the aorta, nearly at right angles with that vessel. They pass
outward and backward, around the sides of the bodies of the lumbar vertebrae, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebrae each artery gives off a **dorsal branch**.

After the formation of the dorsal branch the artery passes outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first lumbar passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest lumbar passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary in front, the intercostals above, and branches of the ilio-lumbar and circumflex iliac below. The lumbar arteries are also distributed to the skin of the sides of the abdomen.

The **Dorsal Branch** (*ramus dorsalis*) gives off, immediately after its origin, a **spinal branch**, which enters the spinal canal. The dorsal branch then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.

The **Spinal Branch** (*ramus spinalis*) enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral (see page 638).

**The Middle Sacral Artery** (*a. sacralis media*) (Fig. 424).—The middle sacral artery is a small vessel, which arises from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body described as Luschka’s gland. It gives off on each side opposite the body of the fifth lumbar vertebra a branch known as the *a. lumbalis ima*. From the middle sacral artery branches arise which run through the mesorectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

**THE COMMON ILIAC ARTERIES (AA. ILIACÆ COMMUNES)** (Figs. 417, 424).

The abdominal aorta divides into the two **common iliac arteries**. The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, each divides opposite the intervertebral substance, between the last lumbar vertebra and the sacrum, into two branches, the **internal and external iliac arteries**, the latter supplying the lower extremity; the former, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestines, branches of the sympathetic nerve, and, at its point of division, the ureter. **Behind**, it is separated from the fourth and fifth
lumbar vertebrae, with the intervening intervertebral disk, by the two common iliac veins. On its outer side, it is in relation with the inferior vena cava and the right common iliac vein, above, and the Psoas magnus muscle below.

The left common iliac is in relation, in front, with the peritoneum, branches of the sympathetic nerve, and the superior hemorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebrae, with the intervening intervertebral disk. The left common iliac vein lies partly on the inner side, and partly beneath the artery; on its outer side, the artery is in relation with the Psoas magnus muscle.

**Plan of the Relations of the Common Iliac Arteries.**

**In front.**
- Peritoneum.
- Small intestines.
- Sympathetic nerves.
- Ureter.

**Outer side.**
- Right Common Iliac.
- Vena cava.
- Right common iliac vein.
- Psoas muscle.

**Inner side.**
- Left common iliac vein.

**Behind.**
- Fourth and fifth lumbar vertebrae.
- Right and left common iliac veins.

**In front.**
- Peritoneum.
- Sympathetic nerves.
- Superior hemorrhoidal artery.
- Ureter.

**Outer side.**
- Left Common Iliac.
- Psoas magnus muscle.

**Branches.**—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar or renal arteries.

**Peculiarities.**—The point of origin varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium, more frequently below than above.

The point of division is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum, being above that point in one case out of eight and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The relative length, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

**Surface Marking.**—Draw a zone around the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

**Surgical Anatomy.**—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage implicating the external or internal iliacs. Now that the surgeon no longer dreads opening the peritoneal cavity, there can be no question that the easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened by an incision in either the semilunar line or the linea alba; the intestines are drawn to one side and the peritoneum covering the artery divided. The sheath is then opened, and the needle passed from within outward. On the right side great care must be exercised in
passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied the incision in the peritoneum over the artery should be sutured. Formerly there were two different methods by which the common iliac artery was tied without opening the peritoneal cavity: 1, an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2, a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length, according to the amount of fat, is made, commencing just outside the middle of Poupart’s ligament and a finger’s breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upward and inward until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar route, making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with the accompanying vein. On the right side both common iliac veins, as well as the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hemorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hemorrhoidal branches of the internal iliac with the superior hemorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

Compression of the Common Iliac Arteries.—The common iliac arteries may be compressed by Davy’s lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden “lever” considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the mesorectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side. In amputation of the hip-joint the common iliac can be compressed most certainly and safely by opening the abdomen and compressing the vessel by means of the fingers against the Psoas muscle (McBurney’s method).

The Internal Iliac Artery (Figs. 417, 424).

The internal iliac or hypogastric artery (a. hypogastrica) supplies the walls and viscera of the pelvis, the generative organs, and sides of the thigh. It is a short thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It arises at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an anterior and posterior; from its anterior division a partially obliterated cord, a part of the foetal hypogastric artery, extends forward to the bladder.

Relations.—In front, with the ureter, which is between the artery and the peritoneum. Behind, with the internal iliac vein, the lumbo-sacral cord, and Pyriformis muscle. By its outer side, near its origin, with the Psoas magnus muscle.
Plan of the Relations of the Internal Iliac Artery.

In front.
Peritoneum.
Ureter.

Outer side.
Psoas magnus.

Behind.
Internal iliac vein.
Lumbo-sacral cord.
Pyriformis muscle.

In the foetus the hypogastric artery is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical
opening, the two arteries twine round the umbilical vein in the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the hypogastric artery; the portion external to that cavity, the umbilical artery.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the superior vesical artery.

Peculiarities as Regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and vice versa.

As Regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen. The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hemorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon the length of the vessel. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or to both the external and internal iliacs at their origin.

A better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis, of New York, on the following grounds: (1) It in no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen's dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the iliolumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and glutal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow's quill, and had a very free anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the sac it was continued down along the back of the thigh nearly as large in size as the femoral, being pervers is about an inch below the sac by receiving an anastomosing vessel from the profunda. The circulation was carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hemorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex

1 Medico-Chirurgical Transactions, vol. xvi.
and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

**Branches** (Fig. 424).—The branches of the internal iliac are:

**From the Anterior Trunk.**
- Superior Vesical.
- Middle Vesical.
- Inferior Vesical.
- Middle Haemorrhoidal.
- Obturator.
- Internal Pudic.
- Sciatic.

**In female**
- Uterine.
- Vaginal.

**From the Posterior Trunk.**
- Ilio-lumbar.
- Lateral Sacral.
- Gluteal.

The **Superior Vesical** (*a. vesicalis superior* (Fig. 424) is that part of the foetal hypogastric artery, which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the *artery of the vas deferens*. Other branches supply the ureter.

The **Middle Vesical** (*a. vesicalis medialis*) (Fig. 424) is usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculae seminales.

The **Inferior Vesical** (*a. vesicalis inferior*) (Fig. 424) arises from the anterior division of the internal iliac, frequently in common with the middle hemorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculae.
THE INTERNAL ILIAC ARTERY

seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The Middle Hæmorrhoidal Artery (a. hæmorrhoidalis media) (Fig. 424) usually arises together with the preceding vessel. It supplies the anus and parts outside the rectum, anastomosing with the other hemorrhoidal arteries.

The Uterine Artery (a. uterina) (Fig. 425) passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance and to the round ligament and the Fallopian tube (ramus tubarius), anastomosing, near its termination, with the ovarian artery. It gives a branch to the ovary (ramus ovarii), which anastomoses with a branch from the ovarian branches to the cervix uteri (cervico-uteri), and a branch which descends on the vagina (cervico-vaginal), and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind; these descend on the anterior and posterior surfaces of the vagina, and are named the azygos arteries of the vagina.

The Vaginal Artery (a. vaginalis) (Fig. 426) is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum. There may be several vaginal arteries. The vaginal artery assists in forming the azygos arteries of the vagina, which are anterior and posterior vessels, running longitudinally, and due to anastomoses of the branches of the vaginal from each side and the cervico-vaginal artery.

Luschka, Hyrtl, Waldeyer, Byron Robinson, and others, instead of describing the ovarian and uterine arteries as two distinct vessels, regard them as constituting

Fig. 426.—The utero-ovarian artery forming the circle described by Byron Robinson.
the chief parts of one vessel, the arteria uterina ovarica. What has been called "the circle of Byron Robinson" is composed of a spiral segment (the arteria uterina ovarica), with a portion of the abdominal aorta, common iliacs, and internal iliacs (Fig. 426).

Byron Robinson\(^1\) has made a careful study of this vascular circle; he shows that it is of great importance in certain surgical procedures, and that its remarkable "capacity for extension" saves it from damage when the uterus is enormously distended by pregnancy, or when it is "drawn through the pudendum with traction forces for palpation, inspection, or repair."

The author just quoted says further that the utero-ovarian artery has three origins, because it develops from the Wolffian body: The ovarian segment arises from the abdominal aorta. The uterine segment arises from the anterior branch of the internal iliac artery. The artery of the round ligament arises from the deep epigastric. The arteria uterina ovarica artery secures nutrition to the uterus by bringing blood from three sources. It is spiral throughout its entire course, in certain parts is convoluted or looped, and it is accompanied by the pampiniform plexus of veins.

The three origins of this vessel are freely united by anastomoses, and rami laterales are given off, which unite the bilateral vessels in the median line. Robinson describes three bifurcations of the utero-ovarian artery. The distal bifurcation, which is "about midway between the uterus and the pelvic wall," and forms an acute angle with the main vessel. This bifurcation indicates the point of division of the external from the internal genitals. The cervico-vaginal artery supplies the external genitals. The proximal bifurcation marks the situation of the ovary. The artery bifurcates at an acute angle into two branches to supply the ovary and Fallopian tube. The middle bifurcation consists of (1) the division of the uterine segment at the angle formed by the uterus and oviduct ("forming the ramus oviductus and ramus ovarii") and (2) the bifurcation of the ramus oviductus forming the ramus oviductus and the ramus ligamenti teretis, or the segment of the round ligament.\(^2\) The relations of the utero-ovarian artery and the ureter are shown in Fig. 426.

**Surgical Anatomy.**—As pointed out by Byron Robinson, the source of bleeding after vaginal hysterectomy is usually the torn and unclamped cervico-vaginal artery.

As previously pointed out, the spiral and convoluted shape of the utero-ovarian artery allows the uterus, ovary, and tube to be drawn into the vagina without injury to the vessels. Byron Robinson points out that in vaginal hysterectomy the genital circle is not divided and only the rami laterales which go to the uterus are cut, the ovaries retaining a normal blood-supply and continuing to functionate.

The Obturator Artery (a. obturatoria) (Fig. 424) usually arises from the anterior trunk of the internal iliac; frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, accompanied by the obturator nerve and vein, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the ascending ramus of the os pubis and the arched border of the obturator membrane, it divides into an internal and external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

**Branches.**—Within the pelvis, the obturator artery gives off an iliac branch (ramus iliacus) to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a vesical branch (ramus vesicalis), which runs backward to supply the bladder; and a pubic branch (ramus pubicus), which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis, communicating with offsets from

the deep epigastric artery and with the corresponding vessel of the opposite side. It is placed on the inner side of the femoral ring. External to the pelvis, the obturator artery divides into an **internal** and an **external branch**, which are deeply situated beneath the Obturator externus muscle.

The **Internal Branch** (*ramus anterior*) curves downward along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The **External Branch** (*ramus posterior*) curves round the outer margin of the obturator foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches: one, smaller, courses inward around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outward in the groove below the acetabulum (*a. acetabulis*), and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

**Peculiarities** (Fig. 427).—In two out of every three cases the obturator arises from the internal iliac; in one case in three and a half from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

![Fig. 427.—Variations in origin and course of the obturator artery.](image-url)

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 427, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 427, B), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The **Internal Pudic Artery** (*a. pudenda interna*) (Figs. 424, 428, and 429) is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **Internal Pudic Artery in the Male** passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles; it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischiorectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and
gradually approaches the margin of the ramus of the ischium, along which it passes forward and upward, pierces the base of the superficial layer of the triangular ligament of the urethra, and runs forward along the inner margin of the ramus of the os pubis, and divides into its two terminal branches, the **dorsal artery of the penis** and the **artery of the corpus cavernosum**.

**Relations.**—In the first part of its course, within the pelvis, it lies in front of the Pyriformis muscle and sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus and overlapped by the great sacro-sciatic ligament. Here the obturator nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the pelvis it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal, the **canal of Alcock**, formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

**Peculiarities.**—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the **accessory pudic**, which generally arises from the internal pudic artery before its exit from the sacro-sciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostatic gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and arteria dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

**Surgical Anatomy.**—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the operation of **lateral lithotomy**. The student should also study the position of the internal pudic artery and its branches, when running a normal course with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this operation, but the hemorrhage from these vessels is seldom excessive; should a ligature be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong obturator fascia under cover of the ramus of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.

**Branches.**—The branches of the internal pudic artery are—the

- **Muscular.**
- **Inferior Haemorrhoidal.**
- **Superficial Perineal.**

**Dorsal Artery of the Penis.**

The **Muscular Branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The **Inferior Haemorrhoidal Artery** (*a. haemorrhoidalis inferior*) arises from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa it is distributed by two or three terminal branches to the muscles and integument of the anal region. Instead of one inferior hemorrhoidal artery two or three small vessels may arise from the internal pudic.

The **Superficial Perineal Artery** (*a. perinei*) (Fig. 428) supplies the scrotum and the muscles and integument of the perineum. It arises from the internal pudic in front
of the preceding branches, and turns upward, crossing either over or under the Transversus perinei superficialis muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perineum it lies beneath the superficial perineal fascia.

The Transverso Perineal Artery is a small branch which arises either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinei muscle. It runs transversely inward along the cutaneous surface of the Transversus perinei superficialis muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the like vessel of the opposite side.

The Artery of the Bulb (a. bulbi urethrae) is a large but very short vessel which arises from the internal pudic between the two layers of the triangular ligament, and, passing nearly transversely inward, between the fibres of the Compressor urethrae muscle, it pierces the bulb of the urethra, which it supplies, and continues anteriorly in the corpus spongiosum to the glans and anastomoses with its fellow of the opposite side. It gives off a small branch which descends to supply Cowper's gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the median or the lateral operation of lithotomy—an accident usually attended in the adult with alarming hemorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perineum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The Artery of the Corpus Cavernosum (a. profunda penis), one of the terminal branches of the internal pudic, arises from that vessel while it is situated between
the two layers of the triangular ligament; it pierces the superficial layer, and, entering the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The Dorsal Artery of the Penis (a. dorsalis penis) ascends between the crus and pubic symphysis, and, piercing the triangular ligament, passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The Internal Pudic Artery in the Female is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum (a. profunda clitoridis) supplies the cavernous body of the clitoris; and the artery dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The Sciatic Artery (a. glutae a inferior) (Fig. 429), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis muscle, and escapes from the pelvis through this foramen between the Pyriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.
Within the pelvis it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hemorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the base and neck of the bladder, vesicle seminales, and prostate gland. External to the pelvis it gives off the following branches:

- Coccygeal.
- Inferior Gluteal.
- Comes Nervi Ischiadici.

The Coccygeal Branch runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The Inferior Gluteal Branches, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The Comes Nervi Ischiadici (a. comitans n. ischiadici) is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

The Muscular Branches supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle; the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The Anastomotic Artery is directed downward across the external rotators and assists in forming the so-called crucial anastomosis by anastomosing with the superior perforating and the internal and external circumflex arteries.

The Articular Branch, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The Ilio-lumbar Artery (a. ilio lumbalis), given off from the posterior trunk of the internal iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The Lumbar Branch (ramus lumbalis) supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch (ramus spinalis) through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the cauda equina.

The Iliac Branch (ramus iliacus) descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The Lateral Sacral Artery (a. sacralis lateralis) (Fig. 424) runs downward. It may be single, but usually there are two on each side, the superior and inferior divisions.

The Superior Division, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, gives spinal branches (rami spinalis) to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The Inferior Division passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral arteries. In its course it gives off spinal branches which
enter the anterior sacral foramina (rami spinales); these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** (*a. glutea superior*) (Fig. 423) is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a **superficial** and **deep branch**. Within the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and, just previous to emerging from that cavity, a nutrient artery, which enters the ilium.

The **Superficial Branch** passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **Deep Branch** runs between the Gluteus medius and minimus, and subdivides into two. Of these, the **superior division** (*ramus superior*), continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The **inferior division** (*ramus inferior*) crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches piece the Gluteus minimus to supply the hip-joint.

**Surface Marking.**—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward: the point of emergence of the gluteal artery from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the sciatic and pudic arteries from the great sciatic notch.

**Surgical Anatomy.**—Any of these three vessels may require ligating for a wound or for aneurism, which is generally traumatic. The gluteal artery is ligated by turning the patient two-thirds over on his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the Gluteus maximus muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the gluteus medius and Pyriformis are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligation of the sciatic artery, the incision should be made parallel with that for ligation of the gluteal, but one inch and a half lower down. After the fibres of the Gluteus maximus have been separated, the vessel is to be sought for at the lower border of the Pyriformis; the great sciatic nerve, which lies just above it, forming the chief guide to the artery. The internal pudic can be reached through the incision used to reach the sciatic.

**The External Iliac Artery** (*A. Iliaca Externa*) (Fig. 424).

The external iliac artery is larger in the adult than is the internal iliac. It passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart's ligament, where it enters the thigh and becomes the femoral artery.

**Relations.**—**In front,** with the peritoneum, subperitoneal areolar tissue or Abernethy's fascia, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is
crossed in this situation by the genital branch of the genito-crural nerve and the deep circumflex iliac vein; the vas deferens curves down along its inner side. **Behind**, it is in relation with the external iliac vein, which, at Poupart's ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. **Externally**, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart's ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

**PLAN OF THE RELATIONS OF THE EXTERNAL ILIAC ARTERY.**

**In front.**

- Peritoneum, intestines, and fascia.
- Lymphatic vessels and glands.
- Spermatic vessels.
- Genito-crural nerve (genital branch).
- Deep circumflex iliac vein.

**Near Poupart's Ligament.**

- External iliac.

**Outer side.**

- Psoas magnus.
- Iliac fascia.

**Inner side.**

- External iliac vein and vas deferens near Poupart's ligament.

**Surface Marking.**—The surface line indicating the course of the external iliac artery has been already given (see page 682).

**Surgical Anatomy.**—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the deep epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upward and outward, parallel to Poupart's ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance. Another mode of ligating the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligated. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligation of the external iliac artery has recently been performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision is made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary, the common iliac artery can be ligated instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligated without in any way interfering with the coverings of the sac of an aneurism. Possibly a disadvantage may exist in the greater risk of hernia after this method.
Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are—the iliolumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sacrotuberous with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligature of the external iliac artery by Sir A. Cooper, the report of which is to be found in Guy's Hospital Reports, vol. i. p. 50, the anastomosing branches are described in three sets: An anterior set.—1, a very large branch from the iliolumbar artery to the circumflex iliac; 2, another branch from the iliolumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3, two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. An internal set.—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. A posterior set.—1, three large branches from the gluteal to the external circumflex; 2, several branches from the sacrotuberous with the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the deep epigastric and deep circumflex iliac arteries.

The Internal or Deep Epigastric Artery (a. epigastrica inferior) (Fig. 424) arises from the external iliac a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the inferior intercostal arteries (Fig. 410). The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it passes to the inner side of the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The cremasteric (a. spermatica externa in the male, a. ligamenti teretis uteri in the female), which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery in the male, and which accompanies the round ligament in the female; a pubic branch (ramus pubicus), which runs along Poupart's ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; muscular branches, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; cutaneous branches perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the deep epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it, or it may arise below this ligament, from the common femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed by two branches, one derived from the external iliac, the other from the internal iliac.
Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart’s ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore internal to an oblique inguinal hernia, but external to a direct inguinal hernia, as the hernia emerges from the abdomen. It forms the outer boundary of Hesselbach’s triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The Deep Circumflex Iliac Artery (a. circumflexa ilium profunda) (Fig. 424) arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart’s ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciae, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to Anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries. It also gives off cutaneous branches.

ARERIES OF THE LOWER EXTREMITY.

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart’s ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial, an arrangement exactly similar to what occurs in the upper limb. For convenience of description, the upper part of the main trunk is named femoral, the lower part, popliteal.

THE FEMORAL ARTERY (A. FEMORALIS) (Figs. 430, 431, 432).

The femoral artery commences immediately behind Poupart’s ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the forepart and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, just on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts the vessel is some distance from the bone. In the upper third of the thigh it is contained in a triangular space called Scarpa’s triangle. In the middle third of the thigh it is contained in an aponeurotic canal called Hunter’s canal.

Scarpa’s Triangle (trigonum femorale).—Scarpa’s triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the inner margin of the Adductor longus, and above by Poupart’s ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus (in some cases a small part of the Adductor brevis), and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery
giving off in this situation its superficial and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. In the outer corner of the space is the external cutaneous nerve. Within the sheath of the artery, and lying upon the outer side of the vessel, is the crural branch of the genito-crural nerve. At the base of the triangle the vein is to the inner side of the artery; at the apex of the triangle it is passing behind the artery. Besides the vessels and nerves, this space contains some fat and lymphatics.

**Fig. 430.**—Scheme of the femoral artery. (Poirier and Charpy.)

**Hunter’s Canal or the Adductor Canal** (canalis adductorius [Hunteri]).—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa’s triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally by the Adductors longus and magnus muscles; and is covered in by a strong aponeurosis which extends transversely from the Vastus internus across the femoral
vessels to the Adductor longus and magnus; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying at first on the outer side and then in front of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the common femoral artery, while the remainder of the vessel is termed the superficial femoral artery, to distinguish it from the deep femoral (profunda femoris), a large branch given off from the common femoral at its termination, and which, by its derivation, from the parent trunk, marks the commencement of the superficial femoral artery.

The Common Femoral Artery
(Figs. 430, 431, 432).

The common femoral artery is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the transversalis fascia, which forms the anterior part of the sheath of the vessels. It has in front of it filaments from the crural branch of the genitocrural nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, being separated from the artery by a small part of the Psoas muscle. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are
enclosed in a strong fibrous sheath formed by the proper sheath of the vessels, strengthened by fascia (see page 509); the artery and vein are separated, however, from one another by a thin fibrous partition.

**Plan of the Relations of the Common Femoral Artery.**

*In front.*
- Skin and superficial fascia.
- Superficial inguinal glands.
- Iliac portion of fascia lata.
- Prolongation of transversalis fascia.
- Crural branch of genito-crural nerve.
- Superficial circumflex iliac vein.
- Superficial epigastric vein.

*Inner side.*
- Femoral vein.

*Outer side.*
- Small part of Psoas muscle, separating the artery from the anterior crural nerve.
- Prolongation of fascia covering the Iliacus muscle.
- Pubic portion of fascia lata.
- Nerve to Pectineus.
- Psoas muscle.
- Pectineus muscle.
- Capsule of hip-joint.

**The Superficial Femoral Artery** (Figs. 430, 431, 432).

The superficial femoral artery is only superficial where it lies in Scarpa’s triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter’s canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and the aponeurotic covering of Hunter’s canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

**Plan of the Relations of the Superficial Femoral Artery.**

- Profunda artery and vein.
- Pectineus muscle.
- Adductor longus.
- Adductor magnus.
The femoral vein, at Poupart's ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The internal saphenous nerve is situated on the outer side of the artery, in the middle third of the thigh, beneath the aponeurotic covering of Hunter's canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities. Double Femoral Reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening of the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great saccro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpia's triangle, or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limbs, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the os pubis by the Pfossus muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The application of a ligature to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral, and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz., the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is on the superficial femoral at the apex of Scarpia's triangle. In order to expose the artery in this situation, an incision between three and four inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein; this must be avoided, and the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to expose fully the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the

1 Ligation of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maudcll, Clin. Soc. Trans., vol. li. p. 37).—Ed. of 15th English edition.
introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery in Hunter's canal, an incision should be made between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh — i.e., midway between the groin and the knee. The integument is first divided. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inward, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery and the long saphenous nerve on the anterior and outer side of the artery.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hemorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

**Collateral Circulation.**—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the glutaeal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligation of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood. The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery.

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemius, and, lastly, with the origin of the anterior and posterior tibial arteries.

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation."

In Porta's work (tab. xii., xiii.) is a good representation of the collateral circulation after the ligation of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anasto-

---

2 Alterazioni patologiche delle Arterie.
motica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular)

which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comites nervi ischiadici of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligation of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death.
The whole of the superficial femoral and popliteal artery seems to have been obliterated. The anastomosis by means of the comes nervi ischiadici, which is shown in Porta’s plate, is distinctly seen: the external circumflex and the termination of the profunda artery seem to have been the chief channels of anastomoses; but the injection has not been a very successful one.

Branches (Figs. 430, 431, and 432).—The branches of the femoral artery are—the

**Superficial Epigastric.**
**Superficial Circumflex Iliac.**
**Superficial External Pudic.**
**Deep External Pudic.**

*Muscular.*

*Anastomotica Magna.*

The **Superficial Epigastric** (a. epigastrica superficialis) arises from the femoral about half an inch below Poupart’s ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **Superficial Circumflex Iliac** (a. circumflexa ilium superficialis), the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart’s ligament, as far as the crest of the ilium, dividing into branches—which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The **Superficial External Pudic** or the **Superior Superficial External Pudic** (a. pudenda externa superficialis) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **Deep External Pudic** or the **Deep Superficial External Pudic** (a. pudenda externa profunda), more deeply seated than the preceding, passes inward across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perineum; and in the female to the labium, anastomosing with branches of the superficial perineal artery.

The **Deep Femoral** or the **Profunda Femoris** (a. profunda femoris) (Figs. 430, 431, and 432) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart’s ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the fourth perforating artery), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

**Relations.**—*Behind,* it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front,* it is separated from the superficial femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side* the origin of the Vastus internus separates it from the femur.
Plan of the Relations of the Profunda Artery.

**In front.**

Branches.—The profunda gives off the following named branches:

Muscular.
External circumflex.
Internal circumflex.
Four perforating.

**Muscular Branches** are given off in Scarpa's triangle, and also from the vessel as it lies between the Adductor muscles.

The **External Circumflex Artery** *(a. circumflexa femoris lateralis)* supplies the muscles on the front of the thigh. It *arises* from the outer side of the profunda, passes horizontally outward, between the divisions of the anterior crural nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—**ascending, transverse, and descending.**

The **ascending branch** *(ramus ascendens)* passes upward, beneath the Tensor fasciae femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries. It sends out muscular branches. The **descending branch** *(ramus descendens)* passes downward, behind the Rectus, upon the Vasti muscles, to which its branches are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus. The **transverse branch,** the smallest, passes outward over the Crureus, pierces the Vastus externus, and winds round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery** *(a. circumflexa femoris medialis)*, smaller than the external, *arises* from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two **muscular branches,** one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward and divides into an ascending and a transverse branch (Fig. 348). The **ascending branch** *(ramus profundus)* passes obliquely upward upon the tendon of the Obturator externus, and under cover of the Quadratus femoris toward the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The **transverse branch** *(ramus superficialis)*, larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries, the **crucial anas-**
tomosis. Opposite the hip-joint the artery gives off an articular vessel (ramus acetabuli), which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The Perforating Arteries (Figs. 429, 430, and 431), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. They pass backward close to the linea aspera of the femur, under cover of small tendinous arches in the Adductor magnus. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The first perforating artery (a. perforans prima) passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces

---

**Fig. 433.—Side view of the popliteal artery.** (From a preparation in the Museum of the Royal College of Surgeons of England.)
the Adductor magnus close to the linea aspera. It gives off branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and middle perforating arteries. The second perforating artery \(a. \text{ perforans secunda}\), larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the first and third perforating arteries. The second artery frequently arises in common with the first. The nutrient artery of the femur is usually given off from this branch. The third perforating artery \(a. \text{ perforans tertia}\) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal. A fourth perforating artery is represented by the termination of the profunda femoris artery.

The nutritive artery of the femur \(a. \text{ nutricia femoris}\), if single, comes from the second perforating artery; if double, from the first and third perforating arteries. If double, one vessel is called superior and the other inferior.

Muscular Branches \(\text{rami musculares}\) are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The Anastomotica Magna \(a. \text{ genu suprema}\) (Figs. 430, 431, and 433) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a superficial and deep branch.

The Superficial Branch \(\text{ramus saphenus}\) pierces the aponeurotic covering of Hunter’s canal, and accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular artery.

The Deep Branch \(\text{ramus musculoarticularis}\) descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and the anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

**THE POPLITEAL ARTERY (A. POPLITEA)** (Figs. 429, 430, 433).

The popliteal artery commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle divides into the anterior and posterior tibial arteries. A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

**The Popliteal Space** (Fig. 434).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 345, page 522.

Boundaries.—The popliteal space, or the ham, is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of
the femur. It is bounded externally, above the joint, by the Biceps, and below the joint by the Plantaris and external head of the Gastrocnemius. Internally, above the joint, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the upper part of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venae comites, which are usually connected by short transverse branches. More deeply and, at its upper part, close to the surface of the bone is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve.

The popliteal lymphatic glands, four or five in number, are found surrounding the artery; one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.
The Popliteal Artery, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

**Peculiarities in Point of Division.**—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint. The anterior tibial under these circumstances may pass in front of the Popliteus muscle.

**Unusual Branches.**—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

**Surface Marking.**—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

**Surgical Anatomy.**—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing MacEwen’s operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure, to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended
with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the supine position, with the knee flexed and the thigh rotated outward, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fascia divided. The tendon of the muscle is thus exposed, and is to be drawn forward and the hamstring tendons backward. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid is the long saphenous vein in the superficial incision. The upper part of the popliteal artery may also be tied by an incision on the back of the limb, along the outer margin of the Semimembranosus, but the operation is a more difficult one, as the internal popliteal nerve and the popliteal vein are first exposed, and great care has to be exercised in separating them from the artery.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

Branches.—The branches of the popliteal artery are—the

Muscular

Superior.

Inferior or Sural.

Cutaneous.

Superior Internal Articular.

Superior External Articular.

Azygos Articular.

Inferior Internal Articular.

Inferior External Articular.

The Superior Muscular Branches, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and flexor muscles of the thigh, anastomosing with the fourth perforating branch of the profunda.

The Inferior Muscular (aa. surales) are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.

The Cutaneous Branches arise separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein, the superficial sural artery.

The Superior Articular Arteries, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The internal branch (a. genu superior medialis) winds inward beneath the hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and, passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. This branch is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The external branch (a. genu superior lateralis) passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch: the superficial branch supplies the Vastus externus, and anasto-
moses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The Azygos Articular (a. genu media) is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The Inferior Articular Arteries, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The internal branch (a. genu inferior medialis) first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The external branch (a. genu inferior lateralis) passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and a deep plexus. The superficial plexus is situated between the fascia and skin round about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the anastomotica magna, the terminal branch of the profunda, the descending branch from the external circumflex and the anterior recurrent branch of the anterior tibial.

The Anterior Tibial Artery (A. Tibialis Anterior) (Fig. 435).

The anterior tibial artery commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg; it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the dorsalis pedis.

Relations.—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.
The anterior tibial artery is accompanied by two veins, *venae comites*, which lie one on each side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has passed through the opening in the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

**Peculiarities in Size.**—This vessel may be very small, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

**Course.**—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

**Surface Marking.**—Draw a line from the inner side of the head of the fibula to midway between the two malleoli. In this line take a point one inch and a quarter below the head of the fibula, and the portion of the line below this point will mark the course of the artery.

**Surgical Anatomy.**—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, and the deep fascia exposed. The wound must now be carefully dried, its edges retracted, and the white line separating the Tibialis anticus from the Extensor longus digitorum sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anticus separated from adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve on its outer side or on the top of the artery. The nerve should be drawn outward, and the venae comites separated from the artery and the needle passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side and one of the venae comites on either side.

**Branches.**—The branches of the anterior tibial artery are—the

- Posterior Recurrent Tibial. [Muscular.]
- Superior Fibular. [Internal Malleolar.]
- Anterior Recurrent Tibial. [External Malleolar.]
The **Posterior Recurrent Tibial** (a. *recurrens tibialis posterior*) is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **Superior Fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **Anterior Recurrent Tibial** (a. *recurrens tibialis anterior*) arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal, with the anastomotica magna, and the external articular branches of the popliteal, assisting in the formation of the circumpatellar plexus.

The **Muscular Branches** are numerous; they are distributed to the muscles which lie on each side of the vessel, some cutaneous branches piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **Malleolar Arteries** supply the ankle-joint. The internal branch (a. *malleolaris anterior medialis*) arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The external branch (a. *malleolaris anterior lateralis*) passes beneath the tendons of the Extensor longus digitorum and Peroneus
tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

**The Dorsalis Pedis Artery (A. Dorsalis Pedis)** (Figs. 435, 436).

The dorsalis pedis, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the *dorsalis hallucis* and communicating.

---

**Relations.**—This vessel, in its course forward, rests upon the astragalus, navicular, and middle cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its tibial side is the tendon of the Extensor proprius hallucis; on its fibular side, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

And their ligaments.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the dorsalis pedis are—the

Cutaneous. Metatarsal—Interosseous.

Tarsal. Dorsalis Hallucis.

Communicating.

Cutaneous Branches go to the skin of the dorsum and inner surface of the foot.

The Tarsal Artery (a. tarsae lateralis) arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The Metatarsal (a. arcuata) arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the dorsal interosseous arteries (aa. metatarsae dorsales), which pass forward upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes (aa. digitales dorsales). At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the forepart of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.
The Dorsalis Hallucis or the First Dorsal Interosseous (a. dorsalis hallucis) is one of the terminal branches of the dorsalis pedis. It runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The Communicating Artery (ramus plantaris profundus), the other terminal branch of the dorsalis pedis, dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and inosculates with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the arteria magna hallucis, or the princeps hallucis. This artery passes forward along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery (A. Tibialis Posterior) (Fig. 434).

The posterior tibial is an artery of large size, which extends obliquely downward from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the internal and external plantar arteries. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

Relations.—It lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles: at its termination it is covered by the Abductor hallucis muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

Plan of the Relations of the Posterior Tibial Artery.

Outer side.

Posterior tibial nerve, lower two-thirds.

Behind.

Integument and fascia.
Gastrocnemius.
Soleus.
Deep transverse fascia.
Posterior tibial nerve.
Abductor hallucis.

Behind the inner ankle the tendons and blood-vessels are arranged, under cover of the internal annular ligament, in the following order, from within out-
ward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side: and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

**Peculiarities in Size.**—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

**Surface Marking.**—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

**Surgical Anatomy.**—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hemorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision; convex backward, should be made through the integument, about two inches and a half in length, midway between the heel and the inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the vena comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the vena comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendon Achilles. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its vena comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

**Branches.**—The branches of the posterior tibial artery are—the

- **Peroneal.**
- **Nutrient.**
- **Muscular.**
- **Cutaneous.**
- **Communicating.**
- **Internal Calcanean.**

**Malleolar cutaneous.**

The **Peroneal Artery** (a. peronaeae) (Fig. 434) lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, or in the substance of the latter muscle to the lower third of the leg, where it gives off the **anterior peroneal.** It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the **external calcanean.**
Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is covered, in the upper part of its course, by the Soleus and deep transverse fascia; below, by the Flexor longus hallucis.

Deep transverse fascia.
Flexor longus hallucis.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting. The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

Branches.—The branches of the peroneal are—the

Muscular.

Nutrient.
Anterior Peroneal.

Posterior Peroneal.
External Calcanean.

Muscular Branches.—The peroneal artery in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The Nutrient Artery (a. nutritia fibulae) supplies the fibula.

The Anterior Peroneal (ramus perforans) (Fig. 436) pierces the interosseous membrane, about two inches above the outer malleolus, to reach the forepart of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The Communicating (ramus communicans) is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The Posterior Peroneal passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

External Calcanean (ramus calcaneus lateralis) are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcanean arteries.

Cutaneous Branches come from the posterior tibial and supply the skin of the inner side and back of the leg.
The Nutrient Artery of the tibia (a. nutricia tibiae) arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The Muscular Branches of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The Communicating Branch (ramus communicans), to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The Malleolar or Internal Malleolar (a. malleolaris posterior medialis) lies upon the tibia, sends branches over the inner ankle, and anastomoses with the inner malleolar branch of the anterior tibial.

The Internal Calcanean (rami calcanei mediales) are several large arteries which arise from the posterior tibial just before its division: they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The Internal Plantar Artery (a. plantaris medialis) (Figs. 437 and 438), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch. Small superficial digital branches accompany the digital branches of the internal plantar nerve and join the plantar digital arteries of the three inner spaces. In addition, this vessel gives off numerous cutaneous branches.

Fig. 437.—The plantar arteries. Superficial view. Fig. 438.—The plantar arteries. Deep view.
The **External Plantar Artery** (*a. plantaris lateralis*) (Figs. 437 and 438), much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the **plantar arch** (*arcus plantaris*) (Fig. 438). As this artery passes outward, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius, and as it passes forward to the base of the little toe it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the Interossei muscles opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

**Surface Marking.**—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point—i. e., a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

**Surgical Anatomy.**—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligate it. They must be treated on similar lines to those of wounds of the palmar arches (see page 665). Delorme has shown that the plantar arch may be ligated from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

**Branches.**—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciae in the sole, gives off the following branches:

- **Posterior Perforating.**
- **Digital.**

The **Posterior Perforating** (*rami perforantes posteriores*) are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal interossei muscles, and anastomoses with the interosseous branches from the metatarsal artery.

The **Digital Branches** (*aa. metatarsae plantares*) are four in number, and supply the three outer toes and half the second toe. It will be remembered that the arteria princeps hallucis is the plantar digital branch of the communicating arms in the first interosseous space and supplies the adjacent sides of the great and little toes. The **first digital branch** of the plantar arch passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and short Flexor muscles. The second, third, and fourth run forward along the interosseous spaces, and on arriving at the clefts between the toes divides into **collateral digital branches** (*aa. digitales plantares*), which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the forepart of the corresponding interosseous space, a small branch which inosculates with the interosseous branches of the metatarsal artery. These are the **anterior perforating branches** (*rami perforantes anteriores*).

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the dorsalis pedis.
THE VEINS.

The Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the pulmonary and systemic veins, and an appendage to the systemic, the portal system.

The Pulmonary Veins are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart. The pulmonary veins are four in number.

The Systemic Veins are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart. The systemic veins are the superior vena cava, the inferior vena cava, and the coronary sinus.

The Portal Vein constitutes the portal system. The portal system is in reality an appendage to the systemic venous system. It is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the portal vein or vena portae. This vessel ramifies in the substance of the liver and breaks up into a minute network.
of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are perfectly cylindrical, like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior (Fig. 439). They usually retain, however, about the same calibre as long as they receive no branches, but not so uniformly as do the arteries.

The veins communicate very freely with one another (Fig. 441), especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses (Fig. 440). The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

Histology of the Veins.—As previously stated, capillaries enter into venules or precapillary veins. The venules empty into larger veins. Vein walls are much thinner than arterial walls. A vein has a much thinner media and much less elastic tissue than an artery, and a very strongly developed adventitia. The intima is a connective-tissue layer containing a small number of elastic fibres and lined with endothelium. The media contains some circular muscle fibres and some fine elastic fibres. In some veins the media is thoroughly well developed (veins of the lower extremities), in others it is practically absent (veins of the retina, of the pia mater, of bone, the superior vena cava). The adventitia is dense and strong, and is composed of connective-tissue elastic fibres and non-striated muscle fibres placed longitudinally. Fig. 442 shows a transverse section of part of the wall of a vein. The vein valves (Fig. 439) are composed of intima and contain elastic fibres. The large veins and the veins of medium
size possess vasa vasorum, in the adventitia and to some extent in the media. The walls of veins contain vasomotor nerves. "Small blood-vessels are often surrounded by lymph capillaries and sometimes by endothelium-lined spaces which are in communication with the lymphatic system. These are called perivascular lymph spaces."

The systemic veins are subdivided into three sets: superficial, deep, and sinuses. The Superficial or Cutaneous Veins are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The Deep Veins accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, and peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called venae comites. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of channels formed by a separation of the two layers of the dura mater, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS (V. PULMONALES) (Fig. 443).

The pulmonary veins return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary veins differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the capillary ramifications of the pulmonary artery, and, uniting together, form one vessel for each lobule. These vessels, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three

---

1 Histology and Microscopic Anatomy. By Szymonowicz and MacCallum.
veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are in front, the veins behind, and the bronchi between the two.

At the root of the lung, the veins are in front, the artery in the middle, and the bronchus behind.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta and superior vena cava; the left pass in front of the thoracic aorta with the left pulmonary artery.

**THE SYSTEMIC VEINS.**

The systemic veins may be arranged into three groups: 1. Those of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 2. Those of the lower extremity, abdomen, and pelvis, which terminate in the inferior vena cava. 3. The cardiac veins, which open directly into the right auricle of the heart.

**VEINS OF THE HEAD AND NECK.**

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and interior of the cranium.
Veins of the Exterior of the Head and Face (Fig. 444).

The veins of the exterior of the head and face are—the

Frontal.  
Supraorbital.  
Angular.  
Facial.  

Temporal.  
Internal Maxillary.  
Temporo-maxillary.  
Posterior Auricular.  
Occipital.

The **Frontal Vein** (*v. frontalis*) commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the **nasal arch** (*v. nasofrontalis*). Occasionally the frontal veins join to form a single trunk, which
bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge and join the supraorbital vein, at the inner angle of the orbit, to form the angular vein.

The **Supraorbital Vein** (*v. supraorbitalis*) commences on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipito-frontalis muscle, receiving tributaries from the neighboring structures, and from the frontal vein of the diploë, and joins the frontal vein at the inner angle of the orbit to form the angular vein.

The **Angular Vein** (*v. angularis*), formed by the junction of the frontal and supraorbital veins, runs obliquely downward and outward on the side of the root of the nose, and receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it moreover communicates with the ophthalmic vein, thus establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **Anterior Facial Vein** (*v. facialis anterior*) commences at the side of the root of the nose, being a direct continuation of the angular vein, which is itself formed by the union of the frontal vein and the supraorbital vein. It lies behind and follows a less tortuous course than the facial artery. It passes obliquely downward and outward, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw, with the facial artery to beneath the angle, and unites with the anterior division of the temporo-massillary vein (*v. facialis posterior*) to form the common facial vein.

The **Common Facial Vein** (*v. facialis communis*) is formed by the union of the anterior facial and the anterior division of the temporo-massillary vein, just beneath the angle of the mandible. The vein is covered by the Platysma myoid muscle, runs downward and backward beneath the Stermo-cleido-mastoid muscle, crosses the external carotid artery, and empties into the internal jugular vein at the level of the hyoid line. It receives a large branch at the anterior border of the Sternocleido-mastoid muscle, which comes from the anterior jugular vein in the suprasternal fossa.

**Tributaries of the Anterior and Common Facial Veins.**—The anterior facial vein receives, near the angle of the mouth, communicating tributaries of considerable size, the deep facial or anterior internal maxillary vein, from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. The common facial vein receives the submental; the inferior palatine, which returns the blood from the plexus round the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

**Surgical Anatomy.**—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supraorbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium. These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. And on account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them and so induce a fatal issue.
The **Superficial Temporal Vein** (*v. temporales superficiales*) commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supraorbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. The trunk is joined in this situation by a large vein, the **middle temporal** (*v. temporalis media*), which receives blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The junction of the superficial temporal and the middle temporal veins forms the **common temporal vein** (*v. temporalis communis*), which descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the **temporo-maxillary vein**.

**Tributaries.**—The common temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the **transverse facial** (*v. transversa faciei*), from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the **orbital vein** (*v. orbitalis*), which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The **Pterygoid Plexus** (*plexus pterygoideus*) and the **Internal Maxillary Vein**.—The internal maxillary vein is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the two middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, and alveolar veins, some palatine veins, the sphenopalatine and the inferior dental veins. The **deep temporal veins** (*v. temporales profundae*) come to the pterygoid plexus from the temporal muscle. These branches form a large plexus, the **pterygoid plexus**, which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus is a tributary of the internal maxillary vein, and communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesali, foramen ovale, and foramen lacerum medium, at the base of the skull. The trunk of the internal maxillary vein comes from the plexus, then passes backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The **Temporo-maxillary Vein** (*v. facialis posterior*), formed by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, an anterior, which passes inward to join the facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular.

The **Posterior Auricular Vein** (*v. auricularis posterior*) commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the posterior division of the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The **Occipital Vein** (*v. occipitalis*) commences at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. From the plexus comes one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminating in the suboccipital triangle by becoming continuous with the posterior vertebral vein. Sometimes they are more superficial, and in this case they are tributaries of the
THE BLOOD-VASCULAR SYSTEM

external jugular vein. As the outermost occipital vein passes across the mastoid portion of the temporal bone, it receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck (Fig. 444).

The veins of the neck, which return the blood from the head and face, are—the

- External Jugular.
- Posterior External Jugular.
- Anterior Jugular.
- Internal Jugular.
- Vertebral.

The External Jugular Vein (v. jugularis externa) receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and the posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of, or in front of, the Scalenes anticus muscle. In the neck it is separated from the Sterno-mastoid by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein is crossed about its middle by the superficialis colli nerve, and throughout the upper half of its course is accompanied by the auricularis magnus nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the sinus. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.¹

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the suprascapular and transverse cervical veins. It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The Posterior External Jugular Vein (v. jugularis posterior) commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The Anterior Jugular Vein (v. jugularis anterior) commences near the hyoid bone from the convergence of the inferior coronary, the submental and the mental veins, and communicating branches. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 465). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a

¹ The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia. Anatomically and Experimentally Considered, including the Demonstration of Valves in the Veins of the Neck," in the Edinburgh Medical Journal for November, 1856.—En. of 15th English edition.
transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The Internal Jugular Vein (v. jugularis interna) collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It commences just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 458). At its origin it is somewhat dilated, and this dilatation is called the sinus or gulf of the internal jugular vein (bulbus v. jugularis superior). It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid artery, and then on the outer side of the common carotid artery, and at the root of the neck unites with the subclavian vein to form the innominate vein. Just before its termination it is distinctly dilated (bulbus v. jugularis inferior). The internal jugular vein, at its commencement, lies upon the Rectus capitis lateralis, and behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forward between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward, behind or in front of, the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The internal jugular vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior, and middle thyroid veins. A branch from the cochlea opens into the sinus of the internal jugular vein. A venous plexus from the lateral sinus (plexus venosus caroticus internus) surrounds the internal carotid artery in the carotid canal and empties into the internal jugular vein. At its point of junction with the common facial vein it becomes increased in size. (See Facial Veins, p. 726.)

The Lingual Veins (vv. linguale) (Fig. 445) commence on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the ranine vein, which is a branch of considerable size commencing below the tip of the

---

**Fig. 445.—Veins of the tongue.** (Testut, modified from Hirschfeld.)
tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the internal jugular. The lingual vein receives the sublingual vein and the dorsalis lingue veins.

The Pharyngeal Veins (vv. pharyngea) vary in number. They commence in a minute plexus, the pharyngeal plexus (plexus pharyngeus), at the back part and sides of the pharynx, and, after receiving meningeal tributaries, the meningeal veins (vv. meningea), the Vidian veins (vv. canalis pterygoidei), and the sphenopalatine veins, terminate in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

The Superior Thyroid Vein (v. thyroidea superioris) (Fig. 446) commences in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and cricothyroid veins. Some anatomists teach that there are two superior thyroid veins on each side, the upper vein being the one just considered, the lower vein being the one usually pointed out as the middle thyroid.

The Middle Thyroid Vein (Fig. 448) collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein. Often in
place of the middle thyroid vein there are two veins, the **superior** and **inferior accessory thyroid**. These veins pass into the internal jugular.

![Diagram showing common arrangement of thyroid veins.](image)

**Veins of the Thyroid Gland**\(^1\) (Fig. 447).—On the surface of the thyroid glands the veins form a plexus between the capsule and the gland. A number of veins

\(^{1}\) See Kocher's description in Langenbeck's *Arch. f. klin. Chir.*, vol. xxix., and James Berry's description in his treatise on *Diseases of the Thyroid Gland.*
penetrate the capsule and pass into adjacent trunks. The most important veins coming from the gland are the superior, middle, and inferior thyroids (or instead of the middle thyroid the superior and inferior accessory thyroid) and the thyreoidea ima.

The superior thyroid vein emerges from the summit of the superior horn of the gland, runs along by the superior thyroid artery, and terminates in the internal jugular vein. A large branch which passes along the inner margin of the upper horn and across the upper surface of the isthmus joins the superior thyroid veins of each side. The middle thyroid vein when present emerges from the side of the gland and empties into the internal jugular. This single vein may be replaced by two veins, the superior and inferior accessory thyroid veins. The superior vein emerges from the outer surface of the upper horn somewhat below the apex. The inferior vein comes from the posterior and inferior portion of the gland. Both empty into the internal jugular. The lower surface of the isthmus and the inner side of each inferior horn is drained by two veins. Each vein is called the thyreoidea ima (Kocher). The left vein empties into the left innominate vein. The right vein empties into either the right or left innominate vein. These veins may be very small, may be absent, or may join and form one vein which empties into the left innominate. An inferior thyroid is often also present. It comes from the outer portion of the inferior horn of the gland and empties into the innominate vein.

The facial and occipital veins have been described on pages 726 and 727.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear. This is done in order to prevent septic emboli being carried into the general circulation. This operation has been performed in a number of cases, with satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which has perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and, consequently on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is danger that a portion of the septic clot will be detached and cause septic embolism in the thoracic viscera. If thrombo-phlebitis of the sinus is suspected the mastoid should be opened and cleansed and the sinus should be at once exposed and explored. If the sinus is found to be thrombosed the surgeon should at once proceed to ligate the internal jugular vein, by an incision along the anterior border of the sternomastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligated in two places and divided between. After the vessel has been secured and divided the lateral sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots may be removed by syringing from the sinus through the vein. If hemorrhage occurs from the distal end of the sinus, it can be arrested by careful plunging with antiseptic gauze.

The thyroid veins are small vessels when the gland is of normal size, but become enormous when the gland is much enlarged.

In the operation of thyroideotomy the veins as well as the arteries are ligated before the gland, or rather before one lobe of it is extirpated.

The Vertebral Vein (v. vertebrealis) (Fig. 449) commences by numerous small veins from the intraspinal venous plexuses (plexus venosi vertebrales); these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the foramina in the transverse processes of the cervical vertebrae. The vessels of this plexus unite at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh. Uniting, these two trunks form a single vessel which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves.

On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen. It anastomoses with the
occipital vein and receives muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery.

The Anterior Vertebral or Anterior Deep Cervical Vein commences in a plexus around the transverse processes of the upper cervical vertebrae, descends in company with the ascending cervical artery between the Scaenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The Posterior Vertebral or Posterior Deep Cervical Vein (v. cervicalis profunda) (Fig. 449) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebrae, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë (Venae Diploicae) (Fig. 450).

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, the diploic canals or canals of Breschet (canales diploici [Breschetti]), which are lined by a more or less complete layer of compact tissue. The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or culs-de-sac, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are
united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins and with the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. They are divided into the frontal diploic vein ($v.\ diploica$ $frontalis$), which opens into the supraorbital vein by an aperture in the supraorbital notch and into the superior longitudinal sinus; the anterior temporal diploic vein ($v.\ diploica$ $temporalis$ $anterior$), which is confined chiefly to the frontal bone, communicates with the sphenoparietal sinus and, after escaping by an aperture in the great wing of the sphenoid, opens into one of the deep temporal veins; the posterior temporal, or external parietal diploic vein ($v.\ diploica$ $temporalis$ $posterior$), is between the emissarium parietale and the emissarium mastoideum; and the occipital diploic vein ($v.\ diploica$ $occipitalis$), the largest of the four, which is confined to the occipital bone, and opens into the emissarium occipitale.

The Emissary Veins are considered on page 743.

The Meningeal Veins ($vv.\ meningee$).—They are numerous in the dura mater, are without valves, anastomose freely with each other, do not increase in size as they reach the sinus which receives them, and bear no regular relation to the meningeal arteries. The middle meningeal artery has two vae comites. The other meningeal arteries usually have two apiece, but may have but one. The middle meningeal veins ($vv.\ meningee$ $mediae$) accompany the middle meningeal artery, are united to the sphenoparietal sinus, pass through the foramen spinosum, and join the pterygoid plexus. The other meningeal veins empty into the superior longitudinal sinus and communicate with the plexus of the foramen ovale.

The Cerebral Veins ($Venae$ $Cerebri$).

The cerebral veins are remarkable for the absence of valves and for the extreme thinness of their coats. The coats are thin because they contain no muscular tissue. The cerebral veins may be divided into two sets: the superficial veins, which are placed on the surface, and the deep veins, which occupy the interior of the organ. The veins of the brain do not accompany associated arteries.
The **Superficial** or **Cortical Cerebral Veins** (*venae cerebri externae*) (Fig. 546) ramify upon the surface of the brain, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, **superior**, **median**, and **inferior cerebral veins**.

The **Superior Cerebral Veins** (*vv. cerebri superiores*), eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the great longitudinal fissure, where they receive the median cerebral veins; near their termination they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus in the opposite direction to the course of the current of the blood.

The **Median Cerebral Veins** (*v. cerebri mediana*) return the blood from the convolutions of the mesial surface of the corresponding hemisphere; they open into the superior cerebral veins, or occasionally into the inferior longitudinal sinus.

The **Inferior Cerebral Veins** (*vv. cerebri inferiores*) ramify on the lower part of the outer surface and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the **middle cerebral** or **superficial Sylvian vein** (*v. cerebri media*), commences on the under surface of the temporal lobe, and, running along a portion of the fissure of Sylvius, opens into the cavernous sinus. The **great anastomotic vein of Trolard** or the **superficial communicating vein** establishes a union between the sinuses of the vertex and those of the base of the brain. It comes from one of the superior cerebral veins, passes downward into the fissure of Sylvius, and, by means of the middle cerebral vein, effects a communication with the cavernous sinus. The **posterior anastomotic vein** connects the middle cerebral vein with the lateral sinus. Other veins commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backward.

The **Deep Cerebral, Central, or Ventricular Veins, Veins of Galen** (*venae Galeni, vv. cerebri interna*) (Fig. 548), are two in number. Each is formed by the union of two veins, the **vena corporis striati**, and the **choroid vein**, on either side. The deep cerebral veins run backward, parallel with one another, between the layers of the velum interpositum, and in the region of the pineal body unite to form one vein, the **vena magna Galeni** (*v. cerebri magna*), which passes out of the brain at the great transverse fissure, between the posterior extremity, or splenium, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two deep cerebral veins receive branches from the callosal region, from a portion of the occipital lobe, and just before their union each vein receives the basilar vein. The vena magna Galeni receives the **vermian vein** from the superficial cerebellar veins.

The **Vena Corporis Steriati** on each side **commences** in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein to form one of the deep cerebral veins.

The **Choroid Vein** (*v. choroidea*) originates in the extreme end of the middle cornu of the lateral ventricle and runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix, and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum to form the deep cerebral vein of that side.

The **Basilar Vein** (*v. basalis*) **commences** at the anterior perforated space at the base of the brain by the union of a small anterior cerebral vein, which courses backward between the anterior lobes of the cerebrum, with the deep Sylvian vein, which descends through the lower part of the Sylvian fissure and receives veins from...
the island of Reil. It passes backward over the crus cerebri, receiving the inferior striate vein from the corpus striatum, interpeduncular veins from the interpeduncular space, ventricular veins from the middle cornu of the lateral ventricles, and tributaries from the uncinate convolution, and enters the vein of Galen just before its junction with the vein of the opposite side.

The **Superficial Cerebellar Veins** (Fig. 546) occupy the surface of the cerebellum, and are disposed in two sets, **superior** and **inferior**.

The **Superior Superficial Cerebellar Veins** (*vv. cerebelli superiores*) pass partly forward and inward, across the superior vermiform process, to terminate in lateral branches which pass partly to the straight sinus and partly outward to the lateral and superior petrosal sinuses.

The **Inferior Superficial Cerebellar Veins** (*vv. cerebelli inferiores*), of large size, terminate in the lateral, inferior petrosal, and occipital sinuses.

The **Deep Cerebellar Veins** bring blood from the interior of the cerebellum to the superficial veins.

**Veins of the Pons Varolii.**—Veins come from the depth of the pons, the deep veins, and empty into a plexus of superficial veins. From this superficial venous plexus a **superior vein** passes to the basilar vein, and an **inferior vein** either into a cerebellar vein or into the superior petrosal sinus.

**Veins of the Medulla Oblongata.**—Veins pass from the depth of the medulla and end in a plexus on the surface. From this plexus comes an anterior median vein, which is a prolongation of a like vein of the spinal cord—a *posterior median vein* corresponding to a like vein of the cord—and small branches which pass with the roots of the ninth, tenth, eleventh, and twelfth cranial nerves, and empty into the occipital and the inferior petrosal sinuses.

The perivascular lymph-spaces are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

**The Sinuses of the Dura Mater (Sinus Durae Matris) (Figs. 451, 452, 453, 456, 457)**

**Ophthalmic Veins and Emissary Veins.**

The sinuses of the dura mater are venous channels, analogous to the veins. The outer coat of a sinus is formed by the dura mater; the inner coat, by a continuation of the lining membrane of the veins. The thick walls of a sinus resist intracranial pressure. They are divided into two sets: (1) those situated at the upper and back part of the skull; (2) those at the base of the skull. The former are—the

- **Superior Longitudinal Sinus.**
- **Inferior Longitudinal Sinus.**
- **Occipital Sinus.**

The **Superior Longitudinal Sinus** (*sinus sagittalis superior*) (Figs. 451, 452, and 453) occupies the attached margin of the falx cerebri. Commencing at the foramen cecum, through which, in the child, it constantly communicates by a small branch with the veins of the nasal fossae, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular on transverse section, is narrow in front, and gradually increases in size as it passes backward. On examining its inner surface it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open

---

1 A. W. Hughes.
chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands, chordæ Willisii (Fig. 453), are also seen extending transversely across the inferior angle of the sinus; and some small, white, projecting bodies, the glandulae Pacchioni (granulationes arachnoidales). This sinus communicates by numerous small apertures with spaces in the dura mater known as lacunæ laterales or parasinoidal spaces (Fig. 453). The Pacchionian bodies project into these spaces. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, the outlets of the parasinoidal spaces, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina. In children a twig from the longitudinal sinus passes through the foramen cæcum and into the nose.

The Torcular Herophili or the confluence of the sinuses (Figs. 452 and 456) is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and
is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus** (*sinus sagittalis inferior*) (Fig. 452), more correctly described as the *inferior longitudinal vein*, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** (*sinus rectus*) (Figs. 451 and 452) is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross-branch with the torcular Herophili. Besides the inferior longitudinal sinus, it receives the vena magna Galeni and the superior cerebellar veins. A few transverse bands cross its interior. This sinus is usually considered to be formed by the union of the great vein of Galen and the inferior longitudinal sinus.

The **Lateral Sinus** (*sinus transversus*) (Figs. 451, 452, 456, and 457) is of large size. There are two lateral sinuses situated in the attached margin of the tentorium cerebelli throughout most of its extent. They commence at
the internal occipital protuberance, one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. Each passes outward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, then, leaving the tentorium, curves downward and inward to reach the jugular foramen, where it terminates in the internal jugular vein. It rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, and the mastoid portion of the temporal bone, and on the occipital again, at the jugular process, just before its termination. The portion of the sinus resting on the mastoid process of the temporal and the jugular process of the occipital bone is not covered by the tentorium and is often called the sigmoid sinus because of its shape, which resembles the letter S. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. The lateral sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal jugular vein (Fig. 457). They communicate with the veins of the pericranium by means of the mastoid and posterior condylloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins, some veins from the diploë, and often veins from the internal ear (vv. auditiva interna), which come out of the internal auditory meatus. The petro-squamous sinus, when present, runs backward along the junction of the petrous and squamous portions of the temporal bone, and opens into the lateral sinus.

**Surgical Anatomy.**—The lateral sinus may, as a result of middle-ear disease, be attacked by suppurative inflammation, which leads to blocking (septic thrombo-phlebitis). In such a case the surgeon will be obliged to open the sinus to remove infected clot and tie the internal jugular vein to intercept thrombi. The lines overlying the sinus is as follows: Draw a line horizontally outward from the occipital protuberance to a point one inch posterior to a vertical line drawn through the external auditory meatus and from this point drop a second line to the mastoid process.

The **Occipital Sinus** (*sinus occipitalis*) (Fig. 452) is the smallest of the cranial sinuses. There is often but a single occipital sinus, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The sinuses at the base of the skull are—the

- Cavernous Sinuses.
- Spheno-parietal Sinuses.
- Circular Sinus.
- Superior Petrosal Sinuses.
- Inferior Petrosal Sinuses.
- Transverse Sinus.

The **Cavernous Sinus** (*sinus cavernosus*) (Figs. 456 and 457) is named from presenting a reticulated structure, due to being traversed by numerous interlacing filaments (Fig. 454). There are two cavernous sinuses, of irregular form, larger behind than in front, and placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. Each receives anteriorly the ophthalmic vein through the sphenoidal fissure, and opens behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division
of the fifth nerve (Fig. 454). These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavernous sinuses receive some of the cerebral veins, and also the sphenoparietal sinuses. They communicate with the lateral sinuses by means of the superior and inferior petrosal sinuses, and with the facial veins through the ophthalmic veins. They also communicate with each other by means of the circular sinus.

**Surgical Anatomy.**—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumor in the orbit. Such a communication may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or it may occur from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the lids and conjunctive. A pulsating tumor develops at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

**The Sphenoparietal Sinus or Sinus Alæ Parvæ (sinus sphenoparietalis).**—Each of these sinuses is lodged in the dura mater on the surface of the lesser wing of the sphenoid bone. It takes origin from one of the middle meningeal veins, usually receives blood from the diploë of the skull, passes inward, and ends in the anterior part of the cavernous sinus.

The **Ophthalmic Veins** are two in number, superior and inferior.

The **superior ophthalmic vein** (v. ophthalmica superior) (Fig. 455) begins as the **naso-frontal vein** (v. nasofrontalis), at the inner angle of the orbit, which communicates with the angular vein. It joins the angular vein with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus. It anastomoses with the inferior ophthalmic vein and receives lachrymal, anterior, and posterior ethmoidal and muscular branches, and veins of the eyelids and of the bulbus oculi.
The **inferior ophthalmic vein** *(v. ophthalmica inferior)* (Fig. 455) arises in the veins of the eyelids and lachrymal sac, receives the veins from the floor of the orbit, and from the portion of the nasal fossa supplied by the anterior and posterior ethmoidal arteries. It either passes out of the orbit through the sphenomaxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or, more frequently, in common with the superior ophthalmic vein. It receives muscular
branches and veins of the bulbus oculi, and anastomoses with the superior ophthalmic vein.

The Circular Sinus (sinus circularis) (Figs. 454 and 456) is formed by two transverse vessels, the anterior and posterior intercavernous sinuses (sinus intercavernous anterior and sinus intercavernous posterior), which connect together the two cavernous sinuses; the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The Superior Petrosal Sinus (sinus petrosus superior) (Figs. 452 and 456) is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives some cerebellar and inferior cerebral veins, and usually veins from the tympanic cavity (vv. auditiva internae).

The Inferior Petrosal Sinus (sinus petrosus inferior) (Figs. 452 and 456) is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital bone. It commences in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen; the junction of these two sinuses forming the commencement of the internal jugular vein. The inferior petrosal sinus receives a vein from the internal ear and also veins from the medulla, pons, and under surface of the cerebellum.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another
in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the foramen with a meningeal branch of the occipital artery, and between the two are the glossopharyngeal, pneumogastric, and spinal accessory nerves (Fig. 457). These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see Fig. 457). These sinuses are semicylindrical in form.

The Transverse or Basilar Sinus (plexus basilaris) (Figs. 456 and 457) consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins (emissaria).—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the diploic veins in the diploë, and the veins external to the skull. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen (emissarium mastoideum) and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A constant vein which passes through the parietal foramen (emissarium parietale) and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condyloid foramen (emissarium condyloideum) and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An Inconstant vein which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein connecting the same parts and passing through the Inconstant foramen of Vesalius at the root of the pterygoid process of the sphenoid bone. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein. 9. A small vein (emissarium occipitale) usually connects the occipital vein with the lateral sinus or the torcular Herophili and the occipital diploic vein.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophtalmic vein at the inner angle of the orbit, and the communication of the veins of the scalp with the diploic veins. Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus by means of the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen caecum, which is another communication between the intracranial and extracranial circulation constantly found in children.
VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the Upper Extremity are divided into two sets, superficial and deep.

The Superficial Veins are placed immediately beneath the integument between the layers of superficial fascia.

The Deep Veins accompany the arteries, and constitute the venæ comites of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial veins.
The Superficial Veins of the Upper Extremity (Fig. 459).

The superficial veins of the upper extremity are—

Superficial Veins of the Hand.  
Anterior Ulnar.  
Posterior Ulnar.  
Common Ulnar.  
Radial.  
Median.  
Median Cephalic.  
Median Basilic.  
Basilic.  
Cephalic.

The Superficial Veins of the Hand and Fingers (Figs. 458 and 459) are principally situated on the dorsal surface. These dorsal veins begin in each finger as a venous plexus, in which are distinct veins running in a longitudinal direction, and called dorsal digital veins (vv. digitales dorsales propriæ). The dorsal digital veins terminate over the first phalanges, in the venous arches of the fingers (arcus venosi digitales). From these arches take origin the four dorsal interosseous or the interdigital veins (vv. metacarpeæ dorsales). These veins form the dorsal venous plexus of the hand (rete venosum dorsale manus). This plexus lies in a line with the lower ends of the shafts of the metacarpal bones. It receives the dorsal interosseous veins, the radial digital vein of the index finger, and numerous superficial veins from the back of the hand. It gives origin to the superficial radial vein and the posterior ulnar vein. The superficial veins of the palmar surface are of less diameter than the dorsal veins. They arise from each of the phalanges by a plexus (vv. digitales volares propriæ). Vessels at the edges of the fingers take most of the blood to the dorsal veins. There are also veins in the finger webs (vv. intercapitulares), which take blood from the palm to the dorsum. A superficial plexus, the palmar plexus, lies upon the palmar fascia, the fascia of the thenar eminence, and the fascia of the hypothenar eminence.

The Anterior Ulnar Vein (v. ulnaris anterior) (Fig. 459) commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The Posterior or Dorsal Ulnar Vein (v. ulnaris posterior) (Fig. 458) commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic and helps to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the Abductor minimi digitii muscle.

The Common Ulnar Vein (v. ulnaris communis) (Fig. 459) is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The Radial Vein (v. radialis) (Figs. 459 and 460) commences upon the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. The radial vein soon forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein. Spalteholz considers the ulnar vein as a portion of the basilic and the radial vein a portion of the cephalic.

The Median Vein (v. mediana cubiti) (Fig. 459) ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend
of the elbow it receives a branch of communication from the deep veins, the **deep median vein**, and divides into two branches, the **median cephalic** and **median basilic**, which diverge from each other as they ascend.

The **Median Cephalic** (v. *mediana cephalica*) (Fig. 459), usually the smaller of the two, passes outward in the groove between the Supinator longus and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** (v. *mediana basilica*) (Fig. 459) passes obliquely inward, in the groove between the Biceps and Pronator radii teres muscles, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion, the **bicipital fascia**, which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.¹

**Venesection** is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

The **Basilic Vein** (v. *basilica*) (Figs. 460 and 462) is of considerable size and is formed by the coalescence of the common ulnar vein with the median

---

¹ Cruveilhier says: "Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic."—Ed. of 16th English edition.
basilic. It passes upward along the inner side of the Biceps muscle and pierces the deep fascia a little below the middle of the arm. The opening in the fascia is known as the **semilunar hiatus** (*hiatus semilunaris*). The vein ascends in the course of the brachial artery to the lower border of the tendons of the Latissimus dorsi and Teres major muscles, and is continued onward as the axillary vein.

The **Cephalic Vein** (v. cephalica) (Fig. 459) is formed by the union of the median cephalic and the radial veins. It courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending or humeral branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and, crossing the axillary artery, terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

**The Deep Veins of the Upper Extremity** (Fig. 460).

The deep veins of the upper extremity follow the course of the arteries, forming their **venae comites** or companion veins. Usually there is one vein lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two **digital veins** accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venae comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volae, and on the ulnar side terminate in the **deep ulnar veins** (Fig. 460). The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the venae comites of the brachial artery. The venae comites of the brachial communicate by numerous transverse branches, which cross over or under the artery.

The **Interosseous Veins** (Fig. 460) accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venae comites of the ulnar artery.

The **Deep Palmar Veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. At the wrist they receive a dorsal and a palmar tributary from the thumb. The deep palmar veins communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the **deep radial veins** (Fig. 460), which are the venae comites of the radial artery. Accompanying the radial artery the deep radial veins terminate in the venae comites of the brachial artery.

The **Brachial Veins** (v. brachiales) (Fig. 460) are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the Subscapularis muscle they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins. One of the brachial veins empties into the axillary, the other, usually the smaller, generally unites with the basilic.

The **Axillary Vein** (v. axillaris) (Fig. 461) is of large size, and may be regarded as the continuation upward of the basilic vein, or as formed by the fusion of a brachial vein with the basilic vein. If the first view is accepted a brachial vein is described as one of the tributaries of the axillary vein. The axillary vein com-
mences at the lower border of the tendons of the Teres major and Latissimus dorsi muscles, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costocoracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. It receives the brachial veins, the vena comites of the axillary artery except the circumflex veins; and near its termination the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins. The circumflex veins end in the subscapular or one of the brachial veins.

The Long Thoracic Branch (v. thoracialis lateralis) (Fig. 462) receives the thoracico-epigastric vein (v. thoracoepigastrica), which comes all the way from the superficial epigastric or from the femoral vein.

The Costo-axillary Veins (vv. costoaxillares) (Fig. 462) come from the first six intercostal spaces and bring blood from the intercostal veins to the axillary.

Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.
To avoid wounding the axillary vein in the extirpation of glands from the axilla no undue force should be used in isolating the glands. If the vein is found to be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligated above and below.

The Subclavian Vein (v. subclavia) (Figs. 421 and 446), the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind and above, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

An expansion of the aponeurosis of the Subclavius muscle lies upon the vein (Fig. 462).

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

**Tributaries.**—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal
jugular the left subclavian vein receives the thoracic duct (Fig. 463), while the right subclavian vein receives the right lymphatic duct.

The **Innominate** or **Brachio-cephalic Veins** (*vv. anonyma*) (Fig. 464) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** (*v. anonyma dextra*) is a short vessel, an inch in length, which *commences* at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right thyroidea ima and the right superior intercostal veins.

The **Left Innominate Vein** (*v. anonyma sinistra*), about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downward, and unites with the right innominate vein to form the **superior vena cava**. It is in relation, in front, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, left thyroidea ima, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins, and the right thyroidea ima. There are no valves in the innominate veins.

**Peculiarities.**—Sometimes the innominate veins open separately into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein—the **left superior vena cava**, as it is termed—after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition in the adult is due to the persistence of the early foetal condition, and is the normal state of things in birds and some mammals.

The **Internal Mammary Vein** (*v. mammaria interna*) corresponds to the internal mammary artery, follows the course of that vessel, and receives branches corresponding with those derived from it. There are two internal mammary veins in the region of the Triangularis sterni muscle, but above this point the vein is single. The double vein is formed by the union of the venae comites of the superior epigastric

**Fig. 463.**—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)
artery (*vv. epigastricae superiores*) and the venæ comites of the musculo-phrenic artery (*vv. musculophrenicae*). It receives the twelve anterior intercostal veins from the upper six intercostal spaces of the corresponding side—six anterior perforating veins (*rami perforantes*)—veins from the surface of the sternum (*rami sternales*)—muscular veins, and vessels from the mediastinum and pleura. The two veins of each side unite into a single trunk, at the upper margin of the triangularis sterni muscle, which terminates in the innominate vein.

The Vertebral Vein (see p. 732).

The Inferior Thyroid Veins (*vv. thyreoideae inferiores*) (Fig. 464), two, frequently three or four, in number, arise in the venous plexus on the thyroid body (*plexus thyreoideus impar*), communicating with the middle and superior thyroid veins. (See Kocher's views, pages 731 and 732.) Kocher states that two thyroidea ima veins are present, and that inferior thyroid veins may also be present. The veins from the lower portion of the gland form a plexus in front of the trachea, behind the Sterno-thyroid muscles. From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and outward across the innominate artery to open into the right innominate vein, just at its junction with the superior vena cava. The thyroidea ima vein (*v. thyreoidea ima*) passes downward in front of the trachea and terminates in the left innominate vein. These veins receive tributaries from the tracheal veins (*vv. tracheales*), from the oesophageal veins (*vv. oesophageae*), from the inferior laryngeal vein (*v. laryngea inferior*).
The **Intercostal Veins** (*vv. intercostales*) are divided into anterior and posterior intercostals.

The **Anterior Intercostal Veins** are tributaries of the internal mammary or the musculo-phrenic veins (p. 731).

The **Posterior Intercostal Veins** (Fig. 464) number eleven on each side, there being one vein in each intercostal space. Each vein lies in the groove at the lower margin of the rib above the corresponding intercostal artery. On the right side the first posterior intercostal vein crosses the neck of the first rib anteriorly and opens into the vertebral vein or the innominate vein. The first posterior intercostal of the left side follows a like course, and empties into the vertebral or innominate vein. The posterior intercostals of the right side, from the fifth to the eleventh, inclusive, open individually into the vena azygos major. The left upper azygos vein receives the fifth, sixth, seventh, and eighth posterior intercostals of the left side. The left lower azygos vein receives the ninth, tenth, and eleventh left posterior intercostals.

The **Right Superior Intercostal Vein** (*v. intercostalis suprema dextra*) is formed by the union of the second, third, and fourth right posterior intercostals. It passes downward and inward and opens into the vena azygos major.

The **Left Superior Intercostal Vein** (*v. intercostalis suprema sinister*) runs across the transverse aorta and opens into the left innominate vein. It usually receives the left bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. Each posterior intercostal vein obtains branches from the ribs and muscles and also a dorsal branch, which receives blood from the muscles of the back, from in front of the vertebral bodies, from back of the vertebral arches, and from the spinal canal by way of a vein which passes through the intervertebral foramen.

The **Superior Vena Cava** (*v. cava superior*) (Fig. 464) receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It *commences* immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

**Relations.**—*In front*, with the pericardium and process of cervical fascia which is continuous with it: this separates it from the thymus gland and from the sternum; *behind*, with the root of the right lung; on its *right side*, with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **Azygos Veins** connect together the superior and inferior vena cava, taking the place of those vessels in that part of the chest occupied by the heart.

The **Larger or Right Azygos Vein** or the **Vena Azygos Major** (*v. azygos*) (Fig. 464) *commences* opposite the first or second lumbar vertebra by a branch from the right lumbar veins, called the **right ascending lumbar vein** (*v. lumbalis ascendens dextra*); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. Whilst passing through the
aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

**Tributaries.**—It receives the lower ten posterior intercostal veins of the right side, the upper two or three of these opening first of all into the right superior intercostal vein. It receives the azygos minor veins, several cesophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the three upper intercostal spaces, usually form two trunks, named the left lower and the left upper azygos veins.

The **Left Lower or Smaller Azygos Vein** or the **Vena Azygos Minor** (*v. hemiazygos*) (Fig. 464) commences in the lumbar region by a branch from one of the lumbar veins, **ascending lumbar** (*v. lumbalis ascendens*), or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, descending on the left side of the spine as high as the ninth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some cesophageal and mediastinal veins.

The **Left Upper Azygos Vein** (*v. hemiazygos accessorla*) varies inversely with the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually three or four in number, usually the fourth, fifth, sixth, and seventh left posterior intercostal veins. They join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.

**Surgical Anatomy.**—In obstruction of the inferior vena cava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior vena cava, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The **Bronchial Veins** (*vv. bronchiales*) return the blood from the substance of the lungs, except from the smaller bronchial tubes and alveola. The blood from them is received by the pulmonary veins. The bronchial vein of the right side opens into the vena azygos major near its termination. The bronchial vein of the left side opens into the left superior intercostal vein or the left upper azygos vein. The bronchial veins are joined by veins from the trachea and mediastinum.

**The Spinal Veins.**

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column, the **dorsi/spinal veins**.
2. Those situated in the interior of the spinal canal, between the vertebrae and the theca vertebralis, **meningo/rachidian veins**.
3. The veins of the bodies of the vertebrae, **vena basis vertebrae**.
4. The veins of the spinal cord, **medulli/spinal veins**.

1. The **Dorsi/spinal Veins** (*plexus venosi vertebrales externi*) commence by small branches which receive their blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They constitute two plexuses: an **anterior plexus** (*plexus venosi vertebrales anteriores*) upon the vertebral bodies and a **posterior plexus** (*plexus venosi vertebrales posteriores*), which surrounds the spinous processes, the laminae, and the transverse and articular processes of
all the vertebrae. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebrae, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina (vv. intervertebrales). The dorsi-spinal veins terminate by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

![Diagram of the blood vascular system](image)

**Fig. 465.**—Transverse section of a dorsal vertebra, showing the spinal veins.

2. The *Meningo-rachidian Veins* (*plexus venosi vertebrales interni*).—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebrae. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebrae, *anterior longitudinal spinal veins*. The other plexus, *posterior longitudinal spinal veins*, is placed on the inner or anterior surface of the laminae of the vertebrae.

![Diagram of the blood vascular system](image)

**Fig. 466.**—Vertical section of two dorsal vertebrae, showing the spinal veins.

The *Anterior Longitudinal Spinal Veins* (*sinus vertebrales longitudinales*) consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebrae along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by
transverse trunks which pass beneath the ligament. Each transverse trunk receives the large vena basis vertebrae (v. basivertebralis) from the interior of the body of the vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The Posterior Longitudinal Spinal Veins, smaller than the anterior, are situated one on each side, between the inner surface of the laminae and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. The posterior longitudinal veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins. The anterior and posterior longitudinal spinal veins join by numerous branches and really constitute one plexus, the plexus venosi vertebrales interni.

The Intervertebral Veins (vv. intervertebrales) accompany the spinal nerves in the intervertebral foramina, receive veins from the spinal cord, and join the meningo-rachidian and the dorsi-spinal veins.

3. The Veins of the Bodies of the Vertebrae or the Venæ Basis Vertebrae (vv. basivertebrales) emerge from the foramen on the posterior surface of each vertebra and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploe of the cranial bones. These channels lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebrae, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part. They open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. The Veins of the Spinal Cord or the Medulli-spinal Veins (vv. spinales) emerge from the cord substance and enter the pia mater plexus. The pia mater plexus is a minute, tortuous, venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. "In this plexus there are six longitudinal channels—one antero-median, along the anterior fissure—two antero-lateral, immediately behind the anterior nerve roots—two posterolateral, immediately behind the posterior nerve roots—and one postero-median, over the postero-septum." These vessels are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina; where it joins the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS
(Figs. 467, 468).

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep, the superficial veins being placed beneath the

integument, between the two layers of superficial fascia, the deep veins accompanying the arteries, and forming the venae comites of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The Superficial Veins of the Lower Extremity.

The Superficial Veins of the Foot.—On the sole of the foot there is a subcutaneous venous plexus (**rete venosum plantare cutaneum**), from which some branches go to the deep veins, but most of the branches pass around the margins to the dorsum of the foot. There is a transverse venous arch at the root of the toes which receives plantar vessels from the toes and sends branches between the toes (vv. intercapitulares) to the venous arch of the dorsum. On the dorsum of each toe the veins gather into two vessels, known as the dorsal digital veins (**vv. digitales pedis dorsales**). The dorsal digital veins from the opposed margins of two toes unite to form a dorsal interdigital vein. There are four dorsal interdigital veins (**vv. digitales communes pedis**), and they pass into the venous arch of the dorsum. The dorsal digital vein, from the inner surface of the great toe, passes directly into the internal saphenous vein, and the dorsal digital vein, from the outer surface of the little toe, passes directly into the external saphenous vein.

On the dorsum of the foot is a venous arch (**arcus venosus dorsalis pedis [cutaneus]**), situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a plexus on the dorsum of the foot (**rete venosum dorsale pedis cutaneum**). The arch terminates internally in the long saphenous, externally in the short saphenous vein.

The chief superficial veins of the lower extremity are the **internal** or long saphenous and the **external** or short saphenous.

The Internal or Long Saphenous Vein (**v. saphena magna**)(Figs. 467 and 470) commences at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart’s ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening receives the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal planter vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The External or Short Saphenous Vein (**v. saphena parva**) (Fig. 468) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg.
Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle. It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

**Surgical Anatomy.**—The saphenous veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than of those in other parts

---

1 Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on Varicose Disease of the Lower Extremities, p. 24, where there is also a careful and elaborate description of the branches of the saphena veins.)—Ed. of 15th English edition.
of the body, except perhaps the spermatic and hemorrhoidal veins. The course of the internal saphenous is in front of the tip of the inner malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The external saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

The Deep Veins of the Lower Extremity.

The deep veins of the lower extremity accompany the arteries and their branches and are called the *venae comites* of those vessels. The vena comites in the lower extremity pass into one trunk, the *popliteal vein*, whereas in the upper extremity the vena comites continue with the artery to the axilla.

**The Deep Veins of the Foot.**—The **plantar digital veins** (*vv. digitales plantares*) form the **plantar metatarsal veins** (*vv. metatarsae plantares*), which communicate with the veins of the dorsum of the foot by perforating veins and also communicate with the deep venous arch of the sole of the foot (*arcus venosus plantaris profundus*). The plantar arch gives off lateral or external **plantar veins**, which unite with median or internal **plantar veins** to form the posterior tibial veins. On the dorsum of the foot the deep veins begin as the **dorsal metatarsal veins** (*vv. metatarsae dorsales pedis*), which form the vena comites of the dorsalis pedis artery.

The **Posterior Tibial Veins** (*vv. tibiales posterosae*) accompany the posterior tibial artery and are joined by the peroneal veins.

The **Anterior Tibial Veins** (*vv. tibiales anteriores*) are formed by a continuation upward of the vena comites of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The **Popliteal Vein** (*v. poplitea*) (Fig. 469) is formed by the junction of the anterior and posterior tibial veins; it ascends through the popliteal space to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to the outer side of the artery. It receives the **sural veins** from the Gastrocnemius muscle, the articular veins, and the external saphenous vein. The valves in this vein are usually four in number.

The **Femoral Vein** (*v. femoralis*) (Figs. 470 and 471) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart's ligament it is joined by
the profunda femoris ($v$. profunda femoris); near its termination it is joined by the internal saphenous vein. The valves in this vein are four or five in number. The External Iliac Vein ($v$. iliaca externa) (Figs. 464, 471, and 473) commences at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epi-
The **Hypogastric** or **Internal Iliac Vein** (*v. iliacae interna* or *v. hypogastrica*) (Figs. 464, 471, and 473) is formed by the veins corresponding to all the branches of the internal iliac artery except the umbilical branch. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the middle hemorrhoidal veins, the superior vesical plexus and the prostatico-vesical plexus in the male, and the superior vesical, inferior vesical, uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The **Internal Pudic Veins** (*vv. pudendae internae*) (Fig. 471) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the deep dorsal vein of the penis, which opens into the prostatico-vesical plexus.

The **Inferior or External Hæmorrhoidal Veins** (Figs. 472 and 473) collect blood from the anus. They pass outward over the External sphincter muscle, unite with numerous subcutaneous veins, and form larger vessels which join the internal pudic veins.

The **Middle Hæmorrhoidal Veins** (Figs. 472 and 473) help to form the hemorrhoidal plexus, perforate the rectal wall, and empty into the internal iliac vein. These veins, by their anastomoses in the hemorrhoidal plexus, establish a communication between the portal and systemic venous systems.

The **Lateral Sacral Veins** (*vv. sacrales laterales*) (Fig. 471) accompany the lateral sacral arteries and terminate in the internal iliac vein.
The Deep Veins of the Lower Extremity

Surgical Anatomy.—The veins of the hemorrhoidal plexus are apt to become dilated and varicose, and form piles, hemorrhoids. This is due to several anatomical reasons: the vessels are contained in very loose, or connective tissue, so that they obtain less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure: the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hemorrhoidal and portal veins have no valves. The veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defecation, and they are affected by every form of portal obstruction.

The Obturator Vein (v. obturatoriae) (Figs. 471 and 473) follows the course of the obturator artery, lying below the artery as it passes over the side of the pelvis; this vein empties into the front part of the internal iliac vein.

The Sciatic Veins are two in number; they accompany the sciatic artery in the upper part of the back of the thigh, and just before their termination in the internal iliac the two veins unite.

The Gluteal Veins (vv. glutea) are usually two in number, and return to the internal iliac vein the blood that has been distributed by the gluteal artery and its branches.

The Superior Vesical Plexus (Fig. 473) is placed upon the fundus and lateral aspects of the bladder on the external aspect of the muscular coat. It receives vessels from the mucous membrane and from the muscular walls. It empties into the internal pudic vein; in the male it communicates with the prostatico-vesical plexus, and in the female with the inferior vesical plexus.

The Prostatic or the Prostatico-vesical Plexus (Fig. 473) surrounds the prostate gland and the neck of the bladder. It is contained between the rectovesical fascia which surrounds the base and sides of the gland and the true capsule of the gland. It communicates with the superior vesical plexus behind and above, and receives the deep dorsal vein of the penis, which enters the pelvis between the subpubic and triangular ligaments. This plexus receives veins from the seminal vesicles and vasa deferentia. On each side one or more vessels pass
from the prostatico-vesical plexus to the internal iliac vein. The veins composing the prostatic plexus are very liable to become varicose, and often contain hard, earthy concretions called phleboliths.

The Inferior Vesical Plexus exists only in the female, and corresponds to the prostatico-vesical plexus in the male, and surrounds the neck of the bladder and the upper portion of the urethra. It receives the dorsal vein of the clitoris and sends efferents to the internal iliac vein.

Surgical Anatomy.—The prostatico-vesical plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation. In enucleating the prostate the gland is shelled out from its capsule of recto-vesical fascia. The veins of the plexus remain attached to the sheath.

The Dorsal Veins of the Penis.—The Superficial Dorsal Vein of the Penis (Fig. 474) receives blood from the prepuce and runs backward beneath the skin, and divides into two branches which terminate in the superficial external pudic vein.

The Deep Dorsal Vein of the Penis (v. dorsalis penis) (Figs. 473 and 474) is a vessel of large size which returns the blood from the body of that organ. At first it con-
sists of two branches, which are contained in the groove on the dorsum of the penis, and it receives numerous superficial veins and veins from the glans penis and the corpus spongiosum. These vessels unite into a single trunk, which passes between the two parts of the suspensory ligament of the penis, and through an aperture between the subpubic ligament and the apex of the triangular ligament, and divides into two branches, which enter the prostatico-vesical plexus. The dorsal vein of the clitoris corresponds in woman to the dorsal vein of the penis in man, and runs into the inferior vesical plexus.

The Vaginal Plexuses and Veins (Fig. 475).—The vaginal plexuses are placed at the sides of the vagina, being especially developed at the orifice of the canal. They receive vessels from the vaginal walls. The plexuses communicate with the uterine plexus above, with the bulbar veins below, with the inferior vesical plexus in front and with the hemorrhoidal plexus behind. From the upper part of each vaginal plexus comes a vaginal vein which passes to the internal iliac.

The Uterine Plexuses (Fig. 475) are situated along the sides and superior angles of the uterus, between the layers of the broad ligament. They receive the veins from the uterus, which veins are without valves. During pregnancy these veins become large venous canals known as the uterine sinuses, and bring blood from the substance of the placenta. These veins join the ovarian above and the vaginal below, and anastomose with each other. They are not tortuous like the artery.

The Uterine Veins (vv. uterinae) (Fig. 475) arise from the lower part of the plexus, and there are usually two veins on each side and they are without valves. These veins for the first portion of their course are placed in the base and inner portion of the broad ligament; they then pass back with the uterine artery in a peritoneal fold between the back of the broad ligament and the recto-uterine fold (Cunningham); they then pass upward and enter the internal iliac vein.
The Common Iliac Vein (v. iliaca communis) (Figs. 464, 471, and 473) on each side is formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, each vein terminates upon the intervertebral substance between the fourth and fifth lumbar vertebrae, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The right common iliac (v. iliaca communis dextra) is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The left common iliac (v. iliaca communis sinistra), longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The Middle Sacral Veins (Figs. 471 and 472) accompany the corresponding artery along the front of the sacrum, and join to form a single vein (v. sacralis media), which terminates in the left common iliac vein; occasionally in the angle of junction of the two iliac veins. The middle sacral veins communicate with the inferior hemorrhoidal.

The Ilio-lumbar Veins (vv. iliolumbales) receive branches from the iliac fossæ, spinal muscles, and spinal canal. One vein on each side runs with the artery, passes posterior to the psoas muscle, and joins the common iliac vein.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.1

The Ascending or Inferior Vena Cava (v. cava inferior) (Figs. 464 and 471) returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebrae. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove on its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered for a very short distance by the serous layer of the pericardium, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the Eustachian valve (valvula v. cavae [inferioris Eustachii]), which is of large size during fetal life.

Relations.—In front, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which, in most cases, partly and occasionally completely surrounds it; behind, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries; and the right semilunar ganglion; on the left side, with the aorta.

Peculiarities. In Position.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart; in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the rightazygous vein, which is then of large size. In such cases the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

1 See two cases which have been described by Mr. Walsham in the St. Bartholomew's Hospital Reports, vols. xvi. and xvii.—Ed. of 15th English edition.
THE DEEP VEINS OF THE LOWER EXTREMITY

Tributaries.—It receives in its course the following veins:

- Lumbar
- Right Spermatic
- Renal
- Suprarenal
- Phrenic
- Hepatic

The Lumbar Veins (vv. lumbales), four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebrae beneath the Psoas magnus muscle, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins of a side are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebrae, and is called the ascending lumbar vein (v. lumbalis ascendens) (Fig. 464). It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The Spermatic Veins (vv. spermaticae) (Fig. 476) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the spermatic plexus (plexus pampiniformis), which forms the chief
mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle (Fig. 477). The termination of the left spermatic vein

![Diagram of the Blood-Vascular System](image)

**Fig. 477.**—Terminations of the right and left spermatic veins. (Poirier and Charpy.)

is called the emulgent vein. Professor John H. Brinton pointed out that a valve is usually absent in the emulgent vein (Fig. 478), but regularly present in the right spermatic vein.¹ The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

**Surgical Anatomy.**—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz., the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. The left veins more often become varicose than the right veins, probably, as Brinton suggests, because the right spermatic vein practically always has a valve and opens into the vena cava at an acute angle, whereas the left spermatic vein is not unusually desitute of a valve at its opening and passes into the left renal vein at a right angle.

The Ovarian Veins (vv. ovaricae) (Fig. 475) are analogous to the spermatic in the male; they form a plexus near the ovary in the broad ligament and about the Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

¹ See John H. Brinton in the American Journal of the Medical Sciences, and also Handbuch der Topographischen Anatomie, von Joseph Hyrtl. Rivington maintains that a valve is usually found at the orifice of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein. (Journal of Anatomy and Physiology, vol. vii, p. 163).—Ebo. of 15th English edition.
The Renal Veins (*vv. renales*) (Fig. 465) are of large size, and are placed in front of the renal arteries. The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior, and, generally, the left suprarenal veins. It opens into the vena cava a little higher than the right. The *uterovenous triangle* of Byron Robinson is formed by the ureter, the renal veins, and the ovarian veins.

The Suprarenal Veins (*vv. suprarenales*) (Fig. 464) are two in number: that on the right side terminates in the vena cava; that on the left side, in the left renal or in the left phrenic vein.

The Phrenic Veins (*vv. phrenici*) follow the course of the phrenic arteries. The two *superior phrenic veins* (*vv. phrenici superiores*), of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary vein. The two *inferior phrenic veins* (*vv. phrenici inferiores*) follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

The Hepatic Veins (*vv. hepaticae*) commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery, *intrahepatic veins*: these tributaries, gradually uniting into *sublobular veins*; usually form three large hepatic veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from

---

1 The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.—Ed. of 15th English edition.
the left lobe open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins (Fig. 479).

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion (stomach, intestine, and pancreas) and from the spleen. The trunk formed by their union, the Portal Vein (vena portae), enters the liver and ramifies throughout its substance after the manner of an artery and ends in capillaries, from which the blood is collected into the hepatic veins, which terminate in the inferior vena cava. The branches of this vein are in all cases single, and destitute of valves.

The veins forming the portal system are—the

Superior Mesenteric. Inferior Mesenteric.
Splenic. Gastric.
Cystic.

The Superior Mesenteric Vein (v. mesenterica superior) (Fig. 479) returns the blood from the small intestines and from the cecum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portae. It receives the right gastro-epiploic vein. The appendicular vein is a tributary of the superior mesenteric vein.

The Splenic Vein (v. lienalis) (Fig. 479) commences by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portae. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The Inferior Mesenteric Vein (v. mesenterica inferior) (Fig. 479) returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. It lies to the left of the artery, and ascends beneath the peritoneum in the lumbar region; it passes behind the transverse portion of the duodenum and pancreas, and terminates in the splenic vein. Its hemorrhoidal branches, the superior hemorrhoidal veins, inosculate with the middle hemorrhoidal branches of the internal iliac, and thus establish a communication between the portal and the general venous system.¹

The Gastric Veins (vv. gastricae) (Fig. 479) are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former, the pyloric vein (v. pylorica), runs along the lesser curvature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portae. The latter, the gastric or coronary vein (v. coronaria ventriculi), begins near the pylorus,

¹ Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the esophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See Physiological Anatomy, by Todd and Bowman, 1859, vol. ii. p. 348).—Ed. of 15th English edition.
runs along the lesser curvature of the stomach toward the oesophageal opening in the diaphragm, and then passes across the front of the spine from left to right to end in the vena portae, at a point a little above the junction of the pyloric vein.

The **Cystic Vein** (v. cystica) (Fig. 479).—The vena portae generally receives the cystic vein, although that vessel sometimes terminates in the right branch of the vena portae.

---

**Note.**—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

The **Portal Vein** (vena portae) (Fig. 479) is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the head of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the **sinus** of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of
these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the common bile-duct and the hepatic artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, and are surrounded by a quantity of loose areolar tissue, the capsule of Glisson.

The portal vein divides, in the substance of the liver, like an artery, and its minute ramifications end in capillaries, from which the blood is carried to the inferior vena cava by the hepatic veins; these veins also collect the blood which has been brought to the liver by the hepatic artery. It will therefore be seen that the blood which is carried to the liver by the portal vein passes through two sets of capillary vessels—viz.: (1) the capillaries in the stomach, intestine, pancreas, and spleen, and (2) the capillaries of the portal vein in the liver.

### THE CARDIAC VEINS (Fig. 480).

The veins which return the blood from the substance of the heart are—the

- Great Cardiac Vein.
- Posterior Cardiac Vein.
- Left Cardiac Veins.
- Anterior Cardiac Veins.
- Right or Small Coronary Vein.
- Coronary Sinus.
- Venæ Thebesii.

The Great Cardiac or Left Coronary Vein (v. cordis magna) is a vessel of considerable size, which commences at the apex of the heart, and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the left extremity of the coronary sinus, its aperture being guarded by two valves. It receives, in
its course, tributaries from both ventricles, but especially from the left, and also from the left auricle; one of these ascending along the thick margin of the left ventricle is of considerable size, and is called the left marginal vein. The vessels joining the great cardiac vein are provided with valves.

The Posterior or Middle Cardiac Vein (v. cordis media) commences by small tributaries, at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the coronary sinus, its orifice being guarded by a valve. It receives veins from the posterior surface of both ventricles.

The Left Cardiac Vein (v. posterior ventriculi sinistri) receives three or four small vessels, which collect the blood from the posterior surface of the left ventricle. It opens into the lower border of the coronary sinus.

The Anterior Cardiac Veins (vv. cordis anteriores) are three or four small vessels, which collect the blood from the anterior surface of the right ventricle. One of these, the vein of Galen, larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The Right Cardiac or Small Coronary Vein (v. cordis parva) runs along the groove between the right auricle and ventricle, to open into the right extremity of the coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The Coronary Sinus (sinus coronarius) is that portion of the anterior or great cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives most of the veins of the heart. Besides those mentioned it receives the oblique vein of Marshall (v. obliqua atrii sinistri) from the back part of the left auricle, the remnant of the obliterated left Cuvierian duct of the foetus, described by Mr. Marshall. The great coronary sinus terminates in the right auricle, between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the Thebesian valve. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The Venæ Thebesii (venæ cordis minimaæ) are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices, foramina Thebesii (foramina venarum minarum), chiefly on the inner surface of the right auricle.
THE LYMPHATIC SYSTEM.

Lymph is obtained from the blood-plasma. From lymph the body cells obtain food, into lymph they discharge their waste materials, and there is a distinct lymphatic circulation, the constituents of the plasma passing into the perivascular lymph-spaces and returning to the heart by way of the lymphatics and certain veins.

The lymphatic system consists of lymphatic glands—large lymph-vessels, small lymph-vessels (lymphatic capillaries), the perivascular lymph-spaces, the lymph canalicular system, and the body cavities. To this system also belong the lacteal or chyliferous vessels. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that during the process of digestion they contain a milk-white fluid, the chyle, which passes into the blood through the thoracic duct.

The lymph canalicular system is the system of spaces in areolar connective tissue. The spaces are called lymph-spaces. In these spaces lie the cells of the tissue. The larger spaces are lined with endothelium, the smaller spaces are not lined-with endothelium; they form connections with each other by anastomotic channels and constitute a system of spaces and channels which probably join the lymphatic capillaries.

The perivascular lymph-spaces are found around certain blood-vessels. Each space is lined with endothelium, and is joined to other spaces by trabecule of connective tissue. The spaces form a system which joins the lymphatic capillaries. Perivascular lymph-spaces have been demonstrated in the Haversian canals and in the subdural space of the pia mater.

The pleural, pericardial, peritoneal, and synovial cavities belong to the lymphatic system. These cavities are lined by endothelial cells. Beneath the layer of lining cells are lymph-spaces or lymph-vessels, which communicate with the body cavity by means of numerous openings in the lining membrane. These openings are called stomata.

Lymph-capillaries are larger than blood-capillaries, but the diameter of a lymph-capillary is different at different points, at some places being much larger than at others. Lymph-capillaries are formed of flattened endothelial cells. In some situations networks of lymphatic capillaries surround the blood-vessels. The lymph-vessels are called the lymphatics.

The lymphatics have derived their name from the appearance of the fluid contained in their interior (lympha, water). They are also called absorbents, from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation. Larger lymphatics are called trunks and the largest are called ducts.

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them, and they appear milky-white; hence the name Asellius gave them of lacteal veins. They retain a nearly uniform size, and may be cylindrical in shape, but usually are interrupted at intervals by constrictions which give them a knotted, beaded, or sac-like appearance. These constrictions are due to the presence of valves in the interior of the vessel. Lymphatic vessels do not invariably contain valves. Valves (772)
are absent at the starting points of lymphatics, are absent in lymphatic capillaries, are not numerous in the largest ducts (thoracic duct), and are seldom found in visceral lymphatics. The valves are not found in fixed situations and vary in number. Between the ends of the fingers and the axillary glands Sappey counted from sixty to eighty. "They are arranged in pairs and resemble the aortic semilunar valves." The lymphatic capillaries are composed purely of endothelium, but the collecting trunks possess not only an endothelial inner coat, but an investing elasto-muscular coat. Vessels in the subcutaneous connective tissue are devoid of muscle. Lymphatics have been found in nearly every texture and organ of the body which contains blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

A larger lymphatic vessel is composed of three coats. The inner coat is composed of elastic tissue lined with endothelium. The middle coat is composed of elastic and muscular fibres. The external coat is composed of connective tissue intermixed with smooth muscular fibres longitudinally or obliquely placed.

The thoracic duct possesses a subendothelial layer of connective tissue like that found in the arteries, and in the middle coat there is a longitudinal layer of connective tissue. The wall of a smaller lymphatic contains no elastic and no muscular tissue, and consists merely of connective tissue lined with endothelium.

The lymphatics are arranged in superficial and deep sets. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body the lymphatics lie in the submucous areolar tissue throughout the whole length of the gastro-pulmonary and genito-urinary tracts, and in the subserous tissue of the thoracic and abdominal cavities. In the cranial cavity the perivasculare sheaths are lymph-spaces. A plexiform network of minute, closed, capillary lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary blood-vessel plexus. From these networks small collecting vessels emerge, pass to a neighboring gland, and divide into a capillary network in the gland. Numerous small vessels emerge from the gland, which unite into one lymphatic vessel, which joins a larger lymphatic trunk, which empties into a branch of the superior vena cava. The deep lymphatics, fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number and in capacity, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect. The continuous trunks retain the same diameter throughout. As the lymphatic vessels approach their point of discharge their number diminishes, but the calibre of the remainder does not increase in proportion.

The gaps in the connective tissue, the larger of which are lined with endothelium, the smaller of which are devoid of endothelial lining, and all of which communicate with the lymphatic capillaries, are known as lymphatic spaces. It is asserted by some, but is not proved, that the spaces are continuous with the lymph-capillaries. Some hold that lymph gets from the spaces into the capillaries by means of openings in intervening tissue. The perivasculare spaces, the serous cavities, and the ventricles of the brain resemble in function lymphatic structures.

The lymphatic or absorbent glands (lymphoglandulae), named also conglobate glands and lymph-nodes, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. They vary from microscopic dimensions to the size of an olive, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black, the hepatic glands, which are yellow, and the splenic glands, which are brown. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these glands in their passage to the lymphatic ducts. A lymphatic or lacteal vessel, previous to entering a gland, divides into several small branches, which are named afferent vessels (vasa afferentia). As they enter the gland, the external coat of each becomes continuous with the capsule of the gland, and the vessels becoming much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the lymph-sinususes of the gland. There is an extensive sinus beneath the capsule; from this subcapsular sinus numerous branches run inward to a central sinus. From both sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single efferent vessel (vasa efferentia), which, on emerging from the gland, is again invested with an external coat from the gland capsule. The lymph-glands are filters through which lymph and chyle flow. Carcinoma cells are caught in them, and the dissemination of the disease is retarded. In the glands are masses of newly formed leukocytes which attack any bacteria in the lymph or chyle.

The size of the lymphatic glands decreases as age advances, and in very old individuals many glands actually disappear. It is impossible to estimate the number of macroscopic glands. Sappey estimated the number to be from 600 to 700. Glands are embedded in fat and are distinctly movable. Some of them are superficial (above the deep fascia); others are deep (below the deep fascia). Occasionally a gland exists alone, but, as a rule, they are assembled in communities or chains of from eight to twelve, or even more. They are usually arranged around vessels, and often are upon vessels. The glands have a plentiful blood-supply, and contain not only vascular nerves, but definite nerve-plexuses. Besides the glands, the body contains numerous lymphoid areas, which, in structure and function, are allied to lymph-glands (tonsils, Peyer’s patches, etc.).

Surgical Anatomy.—In an operation for cancer it is not sufficient to cut wide of the growth and remove it; it is imperatively necessary to remove the lymphatic glands which receive lymph from the diseased area, and also, when possible, the lymphatic vessels between the cancer and the glands. Glands are diseased very early in cancer, long before they are palpably enlarged, and are usually infected by emboli of cancer cells. The rule is in any cancer, however recent, to regard the associated glands as diseased, whether enlarged or not, and to thoroughly remove them, if possible, in one piece, with the intervening lymph-vessels and the area of primary malignant growth.
THE THORACIC DUCT AND THE RIGHT LYMPHATIC DUCT.

The thoracic duct or the left lymphatic duct (ductus thoracicus) (Figs. 482 and 483) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body below the Diaphragm, and usually, but not always, also receives the lymph from the left side of the body above the Diaphragm. It does not drain the right side of the head and neck, the right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It partly drains the right chest wall. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the receptaculum chyli or the reservoir or cistern of Pecquet (cisterna chyli), which is situated upon the front of the bodies of the first and of the second lumbar vertebrae, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. The receptaculum is absent in some individuals. The thoracic duct ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra it inclines toward the left side, and ascends behind the arch of the aorta on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left subclavian vein at its angle of junction with the left internal jugular vein. It usually opens at the apex of the angle in the superior and outer surface, but may open on the posterior surface. Sometimes it terminates by two branches. Figs. 482
and 485 show the termination of the thoracic duct. The thoracic duct, at its commencement, is about equal in diameter to that of a goose-quill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination, the **ampulla**. It is generally flexuous in its course, the older the person the greater the flexuosiry, and it is constricted at intervals so as to present a varicose appearance. The thoracic duct not infrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or divides into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the
one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves throughout its whole course, but they are more numerous in the upper than in the lower part, and the lower valves are not competent; at its termination it is provided with a pair of competent valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

The common intestinal trunk (truncus intestinalis) (Figs. 483, 484, and 511) empties into the receptaculum and brings lymph from the small intestine (lacteals), the stomach, the pancreas, and the spleen.

Radicals of Origin and Tributaries.—In most individuals the juxta-aortic glands which are placed on each side of the aorta send a vessel upward and inward, which unite to form the thoracic duct. The right vessel is known as the truncus lymphaticus lumbalis dextra. The left vessel is known as the truncus lymphaticus lumbalis sinistra. A vessel from the glands in front of (pre-aortic) and back (retro-aortic) of the aorta empties into each of the above-named vessels. In some cases a large vessel forms from the glands in front of the aorta and helps form the duct. The receptaculum chyli receives the common intestinal lymphatic trunk, which conveys lymph from the small intestine, stomach, spleen, pancreas, and a portion of the liver.

![Diagram](image)

The branches of the left lymphatic duct are (Fig. 483): 1. A descending trunk, which collects lymph from the posterior intercostal glands of the seven lower intercostal spaces. 2. A trunk is formed by vessels coming from the superior juxta-aortic glands beneath the Diaphragm. 3. The lymphatic vessels form the upper five intercostal spaces. 4. The lymphatic vessels form the posterior mediastinal glands and retrosternal glands. 5. The left jugular trunk (truncus jugularis), although this may open directly into the junction of the subclavian and internal jugular veins. 6. In rare cases the thoracic duct receives near its termination the left subclavian trunk (truncus subclavius) and a broncho-mediastinal trunk. As a rule, however, the two last-mentioned trunks empty into the jugulo-subclavian junction separately or as one duct.

The thoracic duct receives the lymph from the extremities, the deep portion of the abdominal wall and of the pelvic wall, the pelvic viscera, the kidneys and suprarenal capsules, the large intestine, the small intestine, the walls of the thoracic cavity, the under surface and anterior portion of the liver, the stomach,
the spleen, the pancreas, the sternal and intercostal glands, the left lung, left side of the heart, trachea, and oesophagus, and often, just before its termination, the lymphatics of the left side of the head and neck, and of the left upper extremity.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The internal coat consists of a single layer of flattened endothelial cells; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. Each endothelial cell is shaped like a lance-head and has serrated

![Diagram of the thoracic duct](image)

borders. The middle coat consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminae of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal. The muscular fibres are intermixed with elastic fibres. The external coat is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The Right Lymphatic Duct (Ductus Lymphaticus Dexter)

(Figs. 482, 486, 487, 511).

A right lymphatic duct is frequently present. It is a short trunk, about half an inch in length and a line or a line and a half in diameter. It is formed by the union of the right jugular, right broncho-mediastinal, and right subclavian trunks. Often on the right side the jugular, subclavian, and broncho-mediastinal trunks

![Diagram of terminal collecting trunks](image)
are double. Usually they open into the junction of the internal jugular and subclavian veins separately. Sometimes they unite and open by one duct, and that is the right lymphatic duct. The orifice of the right lymphatic duct is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

**Tributaries.**—The right lymphatic duct, if present, receives lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung, and the right side of the heart, and from part of the convex surface of the liver.

**LYMPHATICS OF THE CRANIAL REGION, FACE AND NECK.**

It is customary to divide the lymphatics of this region into **intracranial** and **extracranial lymphatics**. The statement is made by Poirier and Cunéo\(^1\) that the brain and its membranes are without lymphatics. They state that there are spaces in the nervous centres comparable to lymphatic channels, but which are not truly lymphatic vessels and which are regarded by most as independent of the lymphatic system. Other writers\(^2\) believe that there are cerebral and meningeal lymphatic vessels. It is highly probable that the perivascular spaces around the cerebral arteries are the beginning of a cerebral lymph system, and that these peri-

---

\(^1\) Article on the Lymphatics in the Treatise on Human Anatomy. By Poirier and Charpy.

\(^2\) Cunningham's Text-book of Anatomy.
vascular lymph-channels pass out of the cranium with the arteries and the internal jugular vein and terminate in the superior deep cervical glands. It is also probable that lymph-spaces surround the meningeal blood-vessels and terminate in the superior deep cervical and the internal maxillary glands.

The extracranial lymphatics are divided into superficial and deep, and the two systems freely communicate. All of these vessels run into glands about the head and neck. The superficial lymphatics take origin in the subcutaneous tissue and superficial muscles. The deep vessels arise in the orbit, mouth, nose, pharynx, esophagus, tongue, larynx, and the muscular, ligamentous, and osseous structures.

The Lymphatic Glands of the Head and Face.

The lymphatic glands of the head and face are as follows:
1. The Occipital.
2. The Posterior Auricular.
3. The Parotid and Subparotid.
4. The Internal Maxillary.
5. The Facial.

The Occipital or Suboccipital Glands (lymphoglandulae occipitales) (Figs. 488 and 493).—There are only two or three of these glands on each side. They are situated beneath the deep fascia, a little in front of the anterior edge of the Trapezius muscle, near to but seldom upon the insertion of the Complexus muscle. They receive lymph from the occipital region of the scalp and from them it is sent to the upper deep cervical glands.

The Posterior Auricular Retro-auricular or Mastoid Glands (lymphoglandulae auriculares posteriores) (Figs. 488, 492, and 493).—There are two of these on each side. They are situated just beneath the lower margin of the Retrahens aurem muscle. They receive lymph from the parietal lymph-vessels, "from the internal
surface of the auricle, with the exception of the lobule, and from the posterior surface of the external auditory meatus. The lymph-vessels from these glands empty into the upper deep cervical glands.

The Parotid Lymph-glands (lymphoglandulae auriculares anteriores) (Figs. 488, 489, and 493) are divided into two groups, the superficial and the deep.

The Superficial Parotid or Pre-auricular Lymph-glands.—The superficial parotid lymph-glands are not the subcutaneous lymph-glands occasionally but very rarely found in this region, and which have been described by Richet, but are lymph-nodes situated between the parotid fascia and the parotid salivary gland. There may be three glands, two glands, or only one gland.

The Deep Parotid Lymph-glands.—The deep parotid lymph-glands are situated within the parotid salivary gland. There are from fifteen to twenty of the deep glands. The parotid glands receive lymph from the eyelids, eyebrows, the root of the nose, upper portion of the cheek, frontal portion of the scalp, temporal portion of the scalp, from the outer surface of the pinna, from the external auditory meatus, from the tympanum, and possibly from the mucous membrane of the nose, the posterior alveolar region of the superior maxillary bone, and the soft palate. Lymphatics pass from the superficial parotid glands into the superficial cervical and the upper deep cervical glands. Lymphatics pass from the deep parotid glands into the upper deep cervical glands.

The Subparotid Glands (lymphoglandulae parotidae).—The subparotid glands lie between the parotid salivary gland and the pharynx, and they are close to the internal carotid artery and the internal jugular vein. They receive lymph from the nasal fossae, naso-pharynx, and Eustachian tube, and send vessels to the upper deep cervical glands.

The Internal Maxillary or Zygomatic Glands (lymphoglandulae faciales profundae) (Fig. 493).—The internal maxillary glands lie in the course of the internal maxillary artery in the anterior pharyngeal wall. They receive vessels from the naso-pharynx, palate, zygomatic fossa, temporal fossa, and orbit. From them vessels go to the upper deep cervical glands.

The Facial Glands or Genial Glands (lymphoglandulae faciales) (Figs. 488, 489, and 490).—The facial glands lie in three groups in the course of the lymphatic vessels which are passing to the submaxillary glands. According to Poirier and Cunéo the supramaxillary or inferior group (Fig. 490) lies upon the outer surface of the mandible, at the anterior margin of the Masseter muscle, and beneath the Platysma myoides. There may be only one or two glands in this group, but often there are ten or twelve. These glands lie about the facial artery and vein and are not constantly present. In many cases a salivary gland, the inframaxillary (Fig. 490), is interposed between the supramaxillary and submaxillary glands. The buccinator, buccal, or middle group (Figs. 490 and 493) is present in about one-third of the subjects and lies upon the outer surface of the Buccinator muscle external to the buccal fascia. Some of these glands are situated in the region where Steno's duct perforates the Buccinator muscle. Others are beneath the posterior fibres of the Zygomaticus major muscle.

The superior group of facial glands (Fig. 490) includes a malar gland, a suborbital gland, and a gland in the naso-genial groove. An anterior gland is sometimes found, subcutaneous, on the outer surface of the Orbicularis oris muscle, the commissural gland.

The Lymphatic Vessels of the Cranial Region (Figs. 487, 493).

The lymphatic vessels of the cranial subcutaneous tissues are divided into anterior, lateral, and posterior. The anterior or frontal terminate in the parotid lymph-glands. The lateral or parietal terminate in the parotid and mastoid lymph-glands. The posterior or occipital terminate in the sterno-mastoid and occipital glands.

The Lymphatic Vessels of the Face, the Interior of the Nose, Tongue, Floor of the Mouth, Pharynx, Larynx, and Thyroid Gland (Figs. 487, 489, 490, 491, 492, 494).

The lymphatic vessels of the face are more numerous than those of the cranial region, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running

1 Article on the Lymphatics in the Treatise on Human Anatomy. By P. Poirier and B. Cunéo.
with the facial vein, pass through the glands on the buccal surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The submaxillary lymph glands receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The lymphatics of the orbit and of the temporal and zygomatic fossa run with the branches of the internal maxillary artery to the maxillary glands, and afterward to the deep cervical glands.

The lymphatics of the nose can be injected from the subdural and subarachnoid spaces. They terminate in the retro-pharyngeal and suprahoid glands. The lymphatics of the tongue (Fig. 491) chiefly accompany the ranine vein first to the lingual glands and from these to the deep cervical glands. The lymphatics from the anterior part of the tongue and floor of the mouth pierce the Mylo-hyoid muscles and so reach the submaxillary lymph-glands (p. 1093). From the upper part of the pharynx the lymphatics pass to the retro-pharyngeal glands; from the lower part of the pharynx to the deep cervical glands. From the larynx two sets of vessels arise: an upper, piercing the thyro-hyoid membrane and joining the upper set of deep cervical glands; and a lower, perforating the crico-thyroid membrane to join the lower set of deep cervical glands. The lymphatics of the thyroid gland accompany the superior and inferior thyroid arteries, and open partly into the upper and partly into the lower set of deep cervical glands.
The Lymphatic Glands of the Neck.

The lymphatic glands of the neck are:
1. The Superficial Cervical, including the external jugular and the superficial anterior cervical.
2. The Submaxillary.
3. The Submental.
4. The Retro-pharyngeal.
5. The Deep Cervical, including the anterior deep cervical.

The Superficial Cervical Glands (lymphoglandulae cervicales superficialia) (Figs. 492 and 493).—The superficial cervical glands are composed of two groups, the external jugular and the superficial anterior cervical glands.

The External Jugular Glands (Figs. 489 and 492).—The external jugular glands are superficial to the Sterno-cleido-mastoid muscle. They are four to six in number and lie along the external jugular vein upon the outer surface of the deep cervical fascia, each gland occupying a depression in the fascia. The sterno-cleido-mastoid muscle is beneath them. They are usually gathered in a group a little below the parotid gland, but sometimes extend to the middle of the vein. They receive vessels from the occipital, the posterior auricular, the parotid, and the submaxillary lymph-glands, from the auricle, and from the skin and subcutaneous structures of the neck. From them lymphatic vessels pass to the upper deep cervical and to the lower deep cervical glands.

The Superficial Anterior Cervical Glands.—The superficial anterior cervical glands lie along the anterior jugular vein and from them vessels pass to the deep cervical glands.

The Submaxillary or Lateral Suprahyoid Glands (lymphoglandulae submaxillares) (Figs. 488, 489, and 493).—The submaxillary glands are in the submaxillary triangle beneath the deep fascia. They number three to six; are embedded in the superficial surface of the sheath of the submaxillary gland, but are not found within the sheath. Occasionally one or two are found in the deep portion of the sheath toward the floor of the mouth. The middle gland of Stahr is situated at the point where the submaxillary group is crossed by the facial artery. This is the largest gland of the group. The submaxillary glands receive vessels from the
"nose, the cheek, the upper lip, and the external part of the lower lip, almost the whole of the gums, and the anterior third of the lateral border of the tongue." They also obtain lymph from the floor of the mouth and from the sublingual and submaxillary salivary glands. They send vessels to the jugular and to the upper deep cervical glands.

The **Submental or Median Supranyoid Glands** (Figs. 488, 491, and 493).—There are usually two glands situated between the anterior bellies of the two digastric muscles and upon the Mylo-hyoid muscle. They receive lymph from the cutaneous surface of the chin, from the cutaneous and mucous surfaces of the central portion of the lower lip, from the central portion of the gums, from the floor of the mouth, and from the tip of the tongue. They send some vessels to the submaxillary lymph-glands, and frequently a gland is interposed on the anterior belly of the Digastric muscle. They send other vessels to the upper deep cervical glands.

The **Retro-pharyngeal or Post-pharyngeal Glands** (Fig. 494).—The retro-pharyngeal glands are placed between the upper lateral portion of the posterior part of the pharynx and the first two cervical vertebrae. Leaf tells us that, as a

---

2 Cunningham's Text-book of Anatomy.
rule, there is but one gland on each side, though two may be present. The retro-
pharyngeal glands lie upon the Rectus capitis anticus major muscle, which sepa-
rates them from the vertebrae. They receive vessels from the muscles and fascia in front of the vertebrae, from the nasal fosse and accessory cavities, from the naso-
pharynx and Eustachian tube, and possibly from the cavity of the tympanum. They send vessels to the upper deep cervical glands.

The Deep Cervical, Carotid, or Sterno-mastoid Glands (lymphoglandulae cervicales profundae) (Figs. 488, 489, 491, 492, 493, and 494).—The deep cervical glands are divided into the upper deep cervical and the lower deep cervical, and are associated with certain accessory glands, including the jugular and superficial anterior cervical, which have been discussed under the head of superficial cervical glands; and the anterior deep cervical and the recurrent glands, which have not yet been studied. The deep cervical chain extends from the apex of the mastoid process of the temporal bone to the junction of the internal jugular and subclavian veins.

The Upper Deep Cervical or Substerno-mastoid Glands (lymphoglandulae cervicales profundae superiores).—The upper deep cervical glands extend from the tip of the mastoid process of the temporal bone to about the region where the common carotid artery is crossed by the Omo-hyoid muscle. One group, the external group, is placed external and posterior to the internal jugular vein. The glands are small and numerous, are embedded in the fatty tissue about the nerves from the deep cervical plexus, and at the posterior margin of the Sterno-
cleido-mastoid muscle constitute a continuous mass passing to join the subclavian glands. Another group, known as the internal group or the internal jugular glands, lie directly upon or close by the outer border of the internal jugular vein. This group forms a chain along the internal jugular vein, and the glands are of larger size than those of the external group. Some glands of this group are beneath the vein. The glands of the internal jugular group communicate freely with each other and with the external group. The external group receives lymph-vessels from the posterior auricular, occipital, and external jugular glands, from the occipital region of the scalp, from the auricle, and from the skin, sub-
cutaneous tissue, and muscles of the upper portion of the neck.¹ The internal group receives lymph-vessels from the retro-pharyngeal, parotid, subparotid, sub-

maxillary, and submental glands, the anterior cervical glands (superficial and deep), and the recurrent glands, and from the tongue, naso-pharynx, larynx, soft palate, roof of the mouth, cæsophagus (cervical portion), nasal fossæ, trachea (cervical portion), and the thyroid gland. The external group terminates in the supraclavicular glands. The internal jugular group terminates in the jugular trunk, which, on the right side, helps to form the right lymphatic duct or empties directly into the junction of the internal jugular and subclavian veins, and on the left side empties directly into the venous junction or into the thoracic duct.

The Lower Deep Cervical or Supraclavicular Glands (lymphoglandulae cervicales profundae inferiores).—The lower deep cervical glands lie along the internal jugular vein in the lower part of its course. They receive lymph-vessels from the superficial cervical glands, the upper deep cervical glands, the axillary glands, the accessory chain, the occipital region of the scalp, the skin of the neck, the lower prevertebral muscles, the skin of the pectoral and mammary regions, and the skin of the arm. The supraclavicular glands send vessels which unite with the vessels of the upper deep glands to form the jugular lymphatic trunk. The jugular trunk on the right side may empty directly into the junction of the internal jugular and subclavian veins or may unite with the subclavian trunk to form the right lymphatic duct. On the left side it may empty into the thoracic duct or directly into the venous junction.

Accessory Chains to the Deep Cervical Glands.—The accessory chains to the deep cervical glands are: 1. The external jugular glands (p. 784). 2. The superficial anterior cervical (p. 784). 3. The prelaryngeal or infralaryngeal glands (Fig. 493) between the Crico-thyroid muscles. They receive lymph from the trachea, larynx, and thyroid gland, and send vessels to the pretracheal glands and to the upper deep cervical glands. 4. The tracheal or pretracheal glands (Fig. 493) lie upon the front of the trachea, receive vessels from the trachea, thyroid body, and prelaryngeal glands, and send vessels to the lower deep cervical glands. Some anatomists speak of the prelaryngeal and the pretracheal glands as the anterior deep cervical glands. 5. The recurrent glands lie on the sides of the cæsophagus and trachea, by the recurrent laryngeal nerves. They receive vessels from the larynx, trachea, cæsophagus, and thyroid gland, and send vessels to the upper and lower deep cervical glands.

The Lymphatic Vessels of the Neck (Figs. 487, 491, 492, 493).

The superficial and deep cervical lymphatic vessels are continuations of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, cæsophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite to form the jugular trunk (Fig. 486), which often terminates, on the left side, in the thoracic duct, and on the right side, in the right lymphatic duct, but which may on either side open directly into the vein.

Surgical Anatomy.—In secondary syphilis there is general enlargement of the lymphatic glands, and in the posterior triangle of the neck the enlarged glands are distinctly palpable. The occipital glands may enlarge because of inflammation or suppuration about the occipital region of the scalp, and the posterior-auricular glands enlarge from inflammation or suppuration of the temporal portion of the scalp, the external ear (except the lobule), and the external auditory meatus. Otorrhœa sometimes causes them to enlarge.

The cervical glands are very frequently the seat of tuberculous disease. This condition is usually preceded by a lesion in those parts from which they receive their lymph. The lesion may be tuberculous or inflammatory. If tuberculous it furnishes bacilli directly to the lymph. If inflammatory it lessens tissue resistance and opens the portals to infection. The glands receive

the lymph from the seat of primary disease and become tuberculous. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. Some years ago Sir Frederick Treves prepared a table to show to what glandular group lymph from each region is sent. The table is practically as follows:

**Scalp.**—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

**Skin of face and neck** = submaxillary, parotid, and superficial cervical glands.

**External ear** = superficial cervical glands.

**Lower lip** = submaxillary and suprahyoid glands.

**Buccal cavity** = submaxillary and upper set of deep cervical glands.

**Gums of lower jaw** = submaxillary glands.

**Tongue.**—Anterior portion = suprahyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

**Tonsils and palate** = upper set of deep cervical glands.

**Pharynx.**—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

**Larynx, orbit, and roof of mouth** = upper set of deep cervical glands.

**Nasal fossae** = retropharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossae enter the parotid glands.

Treves's table indicates the glands usually involved, but the seat of primary disease cannot invariably be affirmed from a knowledge of the seat of glandular involvement, because the course of the lymphatic vessels is sometimes varied from that which usually maintains; for instance, in some cases lymphatics from the right side of the tongue pass to glands in the left side of the neck.

Glands may enlarge directly because of primary inflammation, injury, or tumor, but usually a glandular enlargement is secondary to a bacterial disease or to cancer involving the lymph-vessels which come to the gland. The seat of disease may be distant. Disease of the nasal fossae may cause retropharyngeal abscess or enlargement of the submaxillary glands. Cancer of the breast, stomach, or esophagus may be followed by disease of the cervical glands. Disease of the teeth, tongue, gums, floor of the mouth, and alveolar processes may cause enlargement of the submaxillary and other glands, and disease of the tonsil may lead to enlargement of the glands at the angle of the jaw.

The modern radical surgery of cancer depends on a knowledge of these glandular relations, and consists in thoroughly removing the growth and also the associated lymphatic glands, and, when possible, the lymph-vessels running from the tumor to the glands. The lower deep cervical glands occasionally enlarge secondarily to malignant growths of the abdomen or mediastinum, but this is not due to a direct flow of lymph, as the mediastinal glands do not send vessels to the supracleavicular glands. It is due to blocking of lymphatic vessels and reversal of the lymph-stream, so that lymph containing cancerous cells regurgitates.

A retropharyngeal abscess begins to the side of the pharynx. It enlarges toward the centre rather than from it, because the constrictions of the pharynx limit the outward progress of the pus.

The glands within the parotid salivary gland not unusually become tuberculous, and the surgeon may be led to believe that the salivary gland is the seat of primary disease.

Sometimes, though seldom, after the extensive removal of lymph-glands the region drained by their tributaries becomes the seat of persistent hard oedema (lymph oedema). It used to be thought that wounds of the thoracic duct were of necessity fatal, but it is now known that, unless close to the vein, they are seldom even very dangerous. It may be possible to suture a partly divided duct. In an unsutured wound of the duct recovery follows if a collateral lymphatic circulation is established.

THE LYMPHATICS OF THE UPPER EXTREMIT Y.

The Lymphatic Glands of the Upper Extremity.

The lymphatic glands of the upper extremity are divided into two sets, superficial and deep.

**Superficial Lymphatic Glands** (Figs. 495 and 503).—The superficial lymphatic glands of the upper extremity are few in number and small in size. They lie in the

---

1 Dudley P. Allen's case. See Allen and Briggs, in American Medicine, September 21, 1901.
2 Harvey Cushing, Annals of Surgery, June, 1898.
subcutaneous tissue. They are not receiving depots of great areas, but interrupt lymphatic vessels here and there. The glands in the axilla receive all of the lymphatic vessels, superficial and deep. There may be three sets of superficial glands.

One set, the **ante-cubital glands**, lies in front of the elbow. These glands are often absent. When these glands are present they receive vessels from the anterior portion of the forearm and the middle of the palm. The vessels from them pass upward along the front and inner aspect of the arm.

Another superficial gland lies above the internal condyle. It is the **supratrochlear or supræpitrochlear gland or group of glands**. There is usually but one gland, but there may be two or more. It receives vessels from the inner portion of the hand, the three inner fingers, and the inner portion of the forearm, but, because of free anastomoses, also may receive lymph from any portion of the hand and forearm. Lymph-vessels from the supratrochlear gland pass up along the basilic vein to the axillary glands.
There are sometimes several small glands by the cephalic vein in the groove between the Deltoid and great Pectoral muscles. These are called infracavicular glands. The lymph-tract from the infracavicular glands does not terminate in the axillary glands, but ends in the subclavian glands.

The Deep Lymphatic Glands of the Upper Extremity or the Axillary Glands (lymphoglandulae axillares) (Figs. 495, 496, 497, 498, and 503).—The chief deep glands are situated adjacent to the axillary vessels. There are also a few small glands along the radial, ulnar, and brachial arteries which receive deep lymphatics from bones, muscles, and ligaments, and send lymphatics to the axillary glands. The axillary glands number from fifteen to thirty-five in each axilla. They are embedded in the axillary fat and receive the lymphatic vessels from the upper extremity, from the skin of the upper portion of the chest, from the Pectoral muscles, and from the mammary gland. The following division of the axillary glands is made by Poirier, Cunéo, and Delamare: 1. An external group, the

[Diagram of lymphatic system in the thoracic region]

humeral chain, lying on the inner surface of the vessels and nerves, particularly the axillary vein, to the sheath of which they are adherent. Occasionally one or several of these glands are found beneath the vein. Some of the vessels from these glands pass into the central group of lymph-nodes; others enter the subclavian glands; others pass above the clavicle and terminate in glands situated in that region. 2. An anterior group, the thoracic chain, called also the pectoral glands. One mass of this chain, the supero-internal, is situated in the second or third intercostal space in front of the long thoracic artery and beneath the lower edge of the great Pectoral muscle. Another mass, the infero-external, is situated in the fourth and fifth intercostal spaces along the course of the long thoracic artery. The vessels from this chain end in the central group, and some few of them in the subclavian glands. 3. A posterior group, the scapular chain, lying along the dorsalis scapulae artery in the groove between the Teres major and the Subscapularis muscles. They send vessels

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
to the humeral and central chains. 4. A central group, the intermediate glands, placed near the base of the axilla, between the previously described chains. Their efferent vessels end in the subclavian glands. The glands of the central group in many individuals protrude through the opening in the axillary fascia known as the foramen

of Langer (Fig. 313). 5. A subclavian group, situated above the upper margin of the lesser Pectoral muscle. Most of them are internal to the axillary vein,
"between this vein and the first digitation of the Serratus magnus." The humeral chain and the thoracic chain come together and form the subclavian group of glands situated at the apex of the axilla. From the axillary glands come many vessels which, by anastomosing, form the infraclavicular plexus, they then unite into a trunk, the subclavian trunk, which courses between the subclavian vein and Subclavious muscle. On the right side it empties into the junction of the internal jugular and subclavian vein or unites with the jugular trunk to form the right lymphatic duct. On the left side it may empty into the venous junction or into the thoracic duct.

The Lymphatic Vessels of the Upper Extremity (Figs. 495, 496, 497, 498, 499).

The lymphatic vessels of the upper extremity are divided into the superficial and the deep.

The Superficial Lymphatic Vessels of the Upper Extremity.—The superficial vessels begin as plexuses in the skin and form vessels which ascend in the subcutaneous tissue. These plexuses are particularly plentiful in the palm and palmar surface of the digits (Fig. 499). On each side of each finger two lymph-

![Fig. 499.—Superficial lymphatics of the digits and of the dorsal aspect of the hand. (Cunningham.)](image)

vessels are formed; they ascend toward the hand, cross the dorsum, and anastomose frequently with each other. The vessels from the dorsum of the hand join the lymph-vessels of the forearm, which ascend chiefly along the superficial veins. The lymph-vessels which ascend with the superficial ulnar vein pass into the supratrochlear gland. The vessels which accompany the median veins pass into the ante-cubital or supratrochlear glands. Some of the lymph-vessels on the radial side of the forearm run up along the cephalic vein. All the other lymph-vessels of the upper extremity pass direct to the axillary glands. In the forearm there are about thirty vessels, in the middle of the arm there are from fifteen to eighteen (Sappey).

The Deep Lymphatic Vessels of the Upper Extremity.—The deep lymph-vessels convey the lymph from bone, periosteum, muscle, ligament, etc. They pass up the limb with the chief vessels, there usually being two trunks to each artery. In the arm there are two or three vessels. Some few vessels terminate in the small glands along the radial, ulnar, and brachial arteries, but most of them pass directly to the axillary glands.

Surgical Anatomy.—In malignant diseases, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, or arm, the axillary glands are liable to be found enlarged. In secondary syphilis the supratrochlear gland is found to be enlarged. This gland is subcutaneous and readily palpable when enlarged. Normal axillary glands cannot be palpated.

\textsuperscript{1} The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
The axilla is a passage-way for structures between the neck and the upper extremity, and purulent collections or tumors may extend from the neck into the axilla or from the axilla into the neck.

The axillary glands are involved early in cases of cancer of the mammary gland, and later the lower deep cervical glands are involved, and, as Snow has pointed out, regurgitation of lymph containing cancer cells leads to retrosternal involvement and to secondary cancer of the head of the humerus. In operating for cancer of the breast, follow the principle of Halsted and remove the breast, the skin over it, the muscles and fascia, the lymph-vessels, and the axillary glands in one piece. By this plan thorough removal is possible, and as lymph-vessels containing carcinoma cells are not cut across, the wound is not grafted with malignant epithelial cells. Diseased axillary glands are apt to adhere to the sheath of the vein. In removing cancerous glands, always excise the sheath of the vein.

THE LYMPHATICS OF THE LOWER EXTREMITY.

The Lymphatic Glands of the Lower Extremity.

The lymphatic glands of the lower extremity are divided into two sets, superficial and deep. The superficial are confined to the inguinal region, forming the superficial inguinal lymphatic glands.

The Superficial Inguinal Lymphatic Glands (lymphoglandulae inguinales superficiales) (Figs. 500, 501, 502, and 503).—The superficial inguinal lymphatic glands, placed immediately beneath the integument in Scarpa’s triangle, are of large size, and vary in number from ten to twenty. It is customary to divide these glands into groups according to the region in which they are found. The following division is suggested by Poirier, Cunéo, and Delamare: A horizontal line carried through the saphenous opening divides the glands into two groups, a superior group and an inferior group. A vertical line through the saphenous opening divides each of the two groups into two secondary groups, an external and an internal group. We thus have an external and superior group, and internal and superior group, an external and inferior group, and an internal and inferior group.

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
THE LYMPHATIC SYSTEM

Directly in the saphenous opening there are often several glands constituting a central group.

Leaf points out that a gland usually exists near the saphenous opening, which is interposed between the superficial inguinal and deep inguinal glands. The superior group of glands, sometimes called the oblique group, is so placed that the glands lie with a certain regularity along and below Poupart's ligament, the long axis of each gland corresponding with the direction of the ligament. It is now known that each group of the superficial glands does not receive with regularity the lymph from and only from a definite and accurately determined area. Hence, it is not possible, as was once taught, to determine with certainty the exact situation of a lesion by the group of superficial glands involved. The superficial inguinal glands receive vessels from the skin of the lower extremity, gluteal region, peri-

![Fig. 501.—Glands of the inguinal region with the afferent and efferent lymphatics. (Poirier and Charpy.)](image)

neum, abdominal wall, scrotum, anus, and from the prepuce of the clitoris and penis. Occasionally, though not normally, they receive vessels from the glans penis and glans clitoris. The superficial glands send vessels to the deep inguinal glands and to the external iliac glands, and these vessels penetrate the femoral sheath. The vessels which go to the iliac glands ascend with the femoral vessels. Leaf figures some of the efferent vessels from these glands as terminating directly in the veins of this region.

**Surgical Anatomy.**—The superficial inguinal glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus, in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer scroti, in abscess in the perineum, and in other diseases affecting the integument and superficial structures

1 The Surgical Anatomy of the Lymphatic Glands, 1898.
in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The Deep Lymphatic Glands of the Lower Extremity.—The deep glands are the inguinal, anterior tibial, popliteal, gluteal, and ischiatic.

The Deep Inguinal or Deep Femoral Lymphatic Glands (lymphoglandulae inguinales profundae) (Fig. 503).—The deep inguinal lymphatic glands are beneath the deep fascia. There are only two or three of them, and they lie to the inner side of the femoral vein, the upper gland being in the crural canal and projecting into the pelvis. It is called the gland of Cloquet or the gland of Rosenmüller. The deep inguinal glands receive vessels from the superficial inguinal glands, deep lymphatics from along the femoral vessels, and vessels from the glans penis or clitoris. They send vessels to the ilio-pelvic glands.

The Anterior Tibial Gland (lymphoglandula tibialis anterior) (Fig. 503).—The anterior tibial gland is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation. It receives a deep anterior tibial lymphatic trunk and sends off a vessel to the popliteal glands.

The Popliteal Glands (lymphoglandulae popliteae).—The popliteal glands are embedded in the cellular tissue and fat of the popliteal space and about the peroneal vessels. The juxta-articular gland receives lymph-vessels from the knee-joint. The popliteal glands send vessels to the superficial and deep inguinal glands.

The popliteal glands are divided into three groups: 1. A gland external to the termination of the external saphenous vein, the external saphenous gland. 2. A middle group of three or four glands on the sides of the popliteal vessels. The inferior glands of this group are the intercondyloid glands of Leaf. The superior glands are the supracondyloid glands of Leaf. 3. A gland adherent to the posterior

---

1 The Lymphatics. By Poirier, Camé, and Delamare. Translated and edited by Cecil H. Leaf.
ligament of the knee-joint, the juxta-articular gland of Poirier and Guneo. The external saphenous gland receives vessels which ascend along the external saphenous
vein. The middle group receives vessels from the anterior tibial glands and deep lymphatic vessels which ascend with the posterior tibial.

The Gluteal and Ischiatic Glands.—The gluteal and ischiatic glands are placed, the former above, the latter below, the Pyriformis muscle, resting on their corresponding blood-vessels as they pass through the great sacro-sciatic foramen.

The Lymphatic Vessels of the Lower Extremity (Figs. 502, 503).

The lymphatic vessels of the lower extremity, like the veins, may be divided into two sets, superficial and deep.

The Superficial Lymphatic Vessels of the Lower Extremity.—The superficial lymphatic vessels are placed beneath the integument in the superficial fascia, and are divisible into three sets: trunks which follow the course of the internal saphenous vein, trunks which accompany the external saphenous vein, and trunks from the gluteal region. 1. Trunks which follow the course of the internal saphenous vein arise from a plexus on the dorsum of the foot, which plexus obtains lymphatics from all the toes, the sole, and both borders of the foot. The internal trunks, three or four in number, pass to the superficial inguinal glands. The external trunks run upward and inward and end in the internal trunks. 2. The trunks which follow the external saphenous vein number two or three, and they take origin from the heel and from the posterior half of the outer edge of the foot. They empty into the superficial inguinal glands. 3. The lymph-trunks from the gluteal region join vessels from the anus and enter the superficial inguinal glands.

The Deep Lymphatic Vessels of the Lower Extremity.—The deep lymphatic vessels of the lower extremity are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these glands vessels pass beneath Poupart’s ligament and communicate with the chain of glands surrounding the external iliac vessels. The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

THE LYMPHATICS OF THE PELVIS AND ABDOMEN.

The lymphatics of the pelvis and abdomen constitute a continuous chain, but for convenience of study it is customary to divide them into two groups, which we call, with Poirier and Cunéo, the ilio-pelvic glands and the abdomino-aortic glands; the first group being below and the second above the level of the bifurcation of the aorta into the two common iliac arteries.

The Iliac or Ilio-pelvic Glands (Lymphoglandulae Iliaceae) (Figs. 504, 505).

The ilio-pelvic glands are at the level of the inlet of or in the cavity of the pelvis. They follow the course of the blood-vessels and are divisible into the external iliac, the internal iliac, and the common iliac chains.

The External Iliac Glands.—The external iliac glands form chains around the external iliac vessels. There are three chains of these glands. An external chain of three or four glands lies between the artery and the Psoas muscle.

1 Treatise on Human Anatomy.
The lowest gland of the external chain is called by Poirier and Cunéo the external retro-crural gland (Fig. 504). A middle chain of three glands lies upon the front surface of the external iliac vein. The lowest gland of this group is called by Poirier and Cunéo the middle retro-crural gland. An internal chain of three or four glands is placed to the inner side of the external iliac vein. The lowest gland of this chain is called the internal retro-crural gland, and is close to the upper gland of the deep inguinal chain, the gland of Cloquet. The obturator gland belongs to the inner chain of external iliac glands. The external iliac glands receive vessels from the superficial and deep iliac glands, from the glans penis or glans clitoris, deep lymphatics from the umbilicus and lower part of the belly wall, vessels from the superior portion of the vagina, the uterine neck, the prostate gland, the bladder, the membranous portion of the urethra, and the internal iliac glands, and the obturator gland receives deep lymph-vessels from along the course of the obturator vessels. The external iliac glands send vessels direct to the common iliac glands and also lymphatics to join vessels from the internal iliac glands on their way to the common iliac group. The glands along the deep epigastric artery and those along the deep circumflex iliac artery are accessory chains to the main group of external iliac glands.
The Internal Iliac or Hypogastric Glands.—The internal iliac glands are placed along the internal iliac artery and its branches. The gland on the middle hemorrhoidal artery is called the middle hemorrhoidal gland. The lateral sacral gland is on the lateral sacral artery. The internal iliac glands receive lymph from the pelvic viscera, perineum, and penile portion of the urethra, deep tissues of the posterior portion of the thigh, and from the buttocks. They send vessels to the common iliac glands and also to the external iliac glands.

The Common Iliac Glands.—The common iliac glands are found about the common iliac artery and are divided into an external group, which lies upon the inner edge of the Psoas muscle; a middle group, behind the artery, and an internal group, which lies upon the front of the body of the fifth lumbar vertebra or upon the sacro-vertebral junction. They receive vessels from the external and internal iliac glands and from the pelvic viscera, the vessels from the pelvic viscera ascending to the promontory of the sacrum and containing perhaps, here and there, interrupting glands, known as sacral glands (lymphoglandulae sacrales) (Fig. 511). They also receive lymph-vessels from the lumbo-sacral region. They send vessels to the aortic glands. Some anatomists place the common iliac glands and the glands about the lower portion of the aorta and vena cava in a group called the lumbar glands (lymphoglandulae luminales) (Fig. 511).

The Abdomino-aortic Glands (Figs. 484, 511).

The abdomino-aortic glands are placed about the abdominal aorta. There are twenty-five or thirty of them. They are divided by Poirier, Cunéo, and Delamare.
into the right and left juxta-aortic glands, the retro-aortic glands, and the pre-aortic glands.

The Right Juxta-aortic Glands.—The right juxta-aortic glands are grouped in front of and behind the inferior vena cava, the posterior glands lying upon the Psoas muscle and the adjacent pillar of the Diaphragm. They receive lymph-vessels from the right common iliac glands, from the right testicle or the right half of the uterus, and the right tube, ovary, broad ligament, the right kidney and suprarenal capsule, and also lymph-vessels which pass along the lumbar arteries. They send vessels to the pre-aortic and the retro-aortic glands and the receptaculum chyli.

The Left Juxta-aortic Glands.—The left juxta-aortic glands lie by the side of the abdominal aorta, upon the Psoas muscle, and the left pillar of the Diaphragm. They receive tributaries from the left side corresponding to those received by the glands of the right side, and also send out corresponding efferent vessels, and several additional vessels which pass through the left pillar of the Diaphragm and empty into the thoracic duct.

The Retro-aortic Glands.—The retro-aortic glands are placed beneath the receptaculum chyli and in front of the bodies of the fourth and fifth lumbar vertebrae. They receive lymph-vessels from both juxta-aortic groups, and also from the pre-aortic glands, and they send vessels to the receptaculum chyli.

The Pre-aortic Glands.—The pre-aortic glands lie upon the front of the aorta, and in most subjects are divisible into three groups: an inferior, lying at the origin of the inferior mesenteric artery; a middle, at the origin of the superior mesenteric artery, and a superior, about the coeliac axis, the coeliac glands (lymphoglandulae coeliaca). Glands which are found along the course of all the branches of the abdominal aorta empty into and belong to the group of pre-aortic glands. The pre-aortic glands receive vessels from the juxta-aortic glands and from all the glands along the mesenteric vessels and the coeliac axis and its branches, and receive lymph from the stomach, intestines, liver, pancreas, and spleen. They anastomose with each other and send vessels to the retro-aortic glands and to the receptaculum chyli. Instead of the glands terminating in the receptaculum by separate vessels, the vessels may unite and form a common trunk, the intestinal trunk (truncus intestinalis), which runs along with the common trunk from the juxta-aortic glands, and empties into the receptaculum (Fig. 484).

1. The Glands along the Mesenteric Arteries (lymphoglandulae mesentericae) receive the lymph from the colon, cecum, appendix, ileum, jejunum, duodenum, and perhaps also some from the stomach.

2. The Glands Connected with the Coeliac Axis and its Branches.—There are three groups of these glands: the gastric or coronary, the splenic, and the hepatic (including those of the biliary ducts).

The Gastric Glands (lymphoglandulae gastricae).—One group is situated in the gastro-pancreatic fold; another group is connected with the lesser curvature of the stomach (Fig. 508). Some of them are in the lesser omentum close to insertion of the thicker part upon the stomach, and lie near the ascending branches of the gastric artery, that is to say, upon the vertical portion of the lesser curvature. Others lie within the lesser omentum and accompany the descending branches of the gastric artery, and particularly gather near the point where the gastric artery comes toward the stomach wall. The gastric glands receive lymph from most of the stomach. They send lymph to the upper group of pre-aortic glands, the coeliac glands.

The Splenic Glands (lymphoglandulae pancreaticolienales).—The splenic glands accompany the splenic artery and lie upon the posterior surface of the spleen, between the spleen and pancreas. They receive lymph from the fundus of the stomach, from the spleen, and from the pancreas, and send it to the coeliac glands.
The Hepatic Glands (lymphoglandulae hepaticae).—These glands lie along the hepatic artery, some on the level of the floor of the foramen of Winslow, others by the left side of the portal vein. The authors previously quoted point out that there is a secondary chain of hepatic glands about the right gastro-epiploic artery, the gastro-epiploic chain, and that this comprises a subpyloric group and a retro-pyloric group. The subpyloric group (Fig. 508) is placed in the great omentum below the pylorus, and is usually distinctly separated from it. The retro-pyloric group is not constant. It is placed along the gastro-duodenalis artery back of the pylorus. There is also a group of glands, secondary to the hepatic glands, to the right of or posterior to the cystic duct and the common bile-duets. The hepatic glands proper receive lymph from the liver and send it to the celiac glands. The subpyloric glands receive lymph from the inferior portion of the stomach and from the superior portion of the great omentum. They send lymph to the hepatic glands proper, the retro-pyloric glands, and sometimes also to the glands about the superior mesenteric artery. The retro-pyloric glands receive lymph from the subpyloric glands, from the upper surface and from the posterior surface of the pylorus, and from the duodenum. They send lymph to the hepatic glands proper and sometimes to the glands along the superior mesenteric artery. The glands along the gall-duets empty into the hepatic glands proper.

The Lymphatic Vessels of the Abdomen and Pelvis.

The lymphatic vessels of the abdomen and pelvis may be divided into two sets, superficial and deep.

The Superficial Lymphatic Vessels of the Walls of the Abdomen.—The superficial lymphatic vessels of the walls of the abdomen follow the course of the superficial blood-vessels. The superficial lymphatics are derived from the integument. Those of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands (Figs. 501 and 503). Those from the costal margins of the abdomen terminate in the axillary glands (Fig. 497). The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind around the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superficial inguinal glands (Fig. 501).

The Superficial Lymphatic Vessels of the Gluteal Region.—The superficial lymphatic vessels of the gluteal region turn horizontally around the outer side of the nates, and join the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Scrotum and Perineum.—The superficial lymphatic vessels of the scrotum and perineum terminate in the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Penis.—The superficial lymphatic vessels of the penis occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the prepuce; they all converge to the superficial inguinal glands. Lymph vessels from the glans penis empty into the deep inguinal and the external iliac glands.

In the female the lymphatic vessels of the vulva and prepuce of the clitoris pass to the superficial inguinal glands; those of the glans of the clitoris pass to the deep inguinal and the external iliac glands.

The Deep Lymphatic Vessels of the Abdominal Wall.—The deep lymphatic vessels of the abdominal wall take the course of the principal blood-vessels, and arise from muscular or aponeurotic layers. One set of lymph-vessels runs along with the deep epigastric artery and terminates in the external iliac glands. Another
accompanies the deep circumflex iliac artery, and also terminates in the external iliac glands. Several lymph-vessels accompany the lumbar arteries and empty into the juxta-aortic glands. A vessel accompanies the internal mammary artery and empties into the internal mammary glands. Lymph-vessels of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the external iliac, internal iliac, and common iliac glands, and the glands about the lower portions of the aorta and vena cava.

The Lymphatic Vessels of the Umbilicus.—The lymphatics of the umbilicus are divided into three groups: 1. The cutaneous lymphatics, which are very superficial, and empty into the superficial inguinal glands. The lymphatics of the fibrous nucleus, which pass through the rectus sheath, reach the deep epigastric artery and join the deep lymphatics which come from the muscular and aponeurotic layers of the belly wall. The lymphatics of the aponeurotic margin are in two sets: An anterior set, some of which penetrate the rectus sheath and join the lymphatics from the fibrous nucleus; others of which pass outward, penetrate the external and internal oblique muscles, and join the posterior lymph-vessels from the aponeurotic margin. A posterior set, which forms a collection of vessels on the posterior aspect of the rectus sheath, from which several trunks emerge. One trunk passes outward, penetrates the Transversalis muscle, joins the anterior trunk from the aponeurotic margin, and empties into the external iliac glands. Other ducts run along with the deep epigastric artery and pass into the external iliac glands. Glands lie along the lower portion of these lymph-ducts, and are known as the superior epigastric glands, and a gland may exist in the subperitoneal tissue beneath the umbilicus.

The Lymphatic Vessels of the Peritoneum.—It seems probable that the peritoneal cavity is a lymph-sac and that lymphatics take origin from the peritoneum in several ways. Byron Robinson points out three modes of origin: 1. By stomata between endothelial cells. These stomata are in direct communication with lymph-vessels. 2. By interstitial spaces in the subperitoneal tissue. 3. By a plexiform origin similar to interstitial spaces.

Surgical Anatomy.—The fact emphasized by Byron Robinson that the peritoneum is a great lymph-sac explains the rapid absorption of septic material and the rapid spread of infectious processes. If the exudate clots and blocks the lymph-channels, absorption is slow and life may be saved. If it does not clot, absorption is rapid and death is certain. Whether it clots or not depends on the nature of the bacteria present. Fowler, impressed by the fact that absorption takes place most rapidly from the diaphragmatic region and least rapidly from the pelvic region, advises placing the victim of peritonitis in bed, with his head and body elevated.

The Lymphatic Vessels of the Bladder.—No lymphatics exist in the mucous membrane of the bladder, although they do exist in the mucous membrane of the prostate. There are some lymphatics in the bladder muscle, and numerous lymphatics in the subperitoneal tissue. The network of lymph-vessels in the muscles is connected with the network beneath the peritoneum and prevesical fascia, and collecting trunks come from both the anterior and posterior surfaces of the bladder. The anterior collecting trunks are divided into two sets. One set comes from the inferior portion of the anterior surface and passes outward to terminate in an external iliac gland “between the external iliac vein and the obturator nerve.” The other set comes from the superior and anterior vesical surface, runs upward and outward, and terminates in the external iliac glands. Each set of vessels possesses interrupting lymph-nodes, some of which are directly in front of the bladder.

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf. 2 Poirier, Cunéo, and Delamare. 3 The Peritoneum. 4 George Ryerson Fowler, on Diffuse Septic Peritonitis, in the Medical Record, April 14, 1900. 5 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
The posterior collecting trunks are divided into four sets. The first set comes from the superior and posterior portion and passes outward, exhibiting interrupting nodes in its course. These trunks terminate in the external iliac glands. The second set runs directly back into the external iliac glands. The third set comes from the middle of the posterior portion of the bladder and terminates in the hypogastric glands. The fourth set comes from the vesical neck, passes back and then ascends and terminates in the glands in front of the sacral promontory. This fourth set joins with the lymphatics from the prostate and seminal vesicles.

The Lymphatic Vessels of the Prostate Gland.—These vessels form a peri-prostatic plexus, which receives its afferents from the gland structure. This plexus is drained by four vessels, three of which commence on the posterior surface of the gland. Although these vessels begin on the posterior surface of the prostate, their termination in each case is different. One passes on the under surface of the bladder, crosses the superior vesical artery, runs outward, and ends in the middle chain of the external iliac group. Another passes upward, outward, and backward, and terminates in the hypogastric group. A third passes along the floor of the pelvis, runs by the side of the rectum, and ascends on the anterior surface of the sacrum to terminate in the lateral sacral glands and in the hypogastric group. Occasionally a fourth trunk is found on the anterior surface of the prostate, which descends and joins the vessels from the membranous urethra and ends in the hypogastric glands.

The Lymphatic Vessels of the Male Urethra.—These vessels are divided into two groups: First, those of the penile portion of the urethra; second, those of the bulb and membranous portion. The lymphatics of the prostatic urethra belong to those of the prostate gland. The lymph-vessels of the penile urethra in front of the sulcus all run toward the frenum, at which point they bend backward to the sulcus; here they run to the dorsal surface of the penis and terminate in the same manner as the vessels from the glans. The trunks from the remainder of the penile urethra emerge from the inferior surface, run around the corpus cavernosa, and mostly unite with the vessels from the glans penis. One vessel, though, passes over the symphysis and enters in the internal retro-crural gland, whilst another passes beneath the symphysis and terminates with the vessels from the bulb and membranous portion of the urethra. The lymphatics of the bulb and membranous portions end in three trunks, one of which accompanies first the artery of the bulb and then the internal pudic artery, and ends in the hypogastric gland attached to the pelvic portion of this artery. A second trunk runs behind the pubes, to end in the internal retro-crural gland. A third trunk runs on the bladder, where it joins with vessels from this organ, to end in the internal chain of external iliac glands.

The Lymphatic Vessels of the Female Urethra.—The lymphatics of the female urethra terminate in the same manner as do the lymphatics of the bulb and membranous portions of the male urethra.

The Lymphatic Vessels of the Uterus.—These consist of three sets, each of which arises by a network of capillaries. There is a mucous network, a muscular network, and a peritoneal network. The vessels from these three regions of origin are collected in the subperitoneal tissue, from which area the collecting trunks take origin. From the cervix, according to Poirier and Cunéo, come from five to eight collecting trunks, which pass toward the sides of the body of the uterus, forming on each side, by twisting and dilatation, the juxta-cervical lymphatic knot of Cunéo. The cervical connecting trunks are divisible into three groups on each side. One group is composed of two vessels, which pass to the middle chain of the external iliac glands (superior and middle glands). Another group is composed of two vessels, which enter the hypogastric glands. A third group is composed of several vessels, some of which enter the lateral sacral glands, and the balance of which terminate.
in the glands of the sacral promontory. From the body of the uterus come three groups on each side. One group is composed of four or five vessels which emerge below the uterine cornu, pass beneath the ovary, where they receive the ovarian lymphatics, and terminate in the juxta-aortic glands of the same side. One so-called accessory lymphatic pedicle terminates in the external iliac glands, the other in the inguinal glands.

The Lymphatic Vessels of the Fallopian Tube.—The lymphatics of the Fallopian tube join with those of the uterus and ovary and terminate in the lateral aortic glands.

The Lymphatic Vessels of the Ovary.—The ovary is extremely rich in lymphatics; they form a plexus which is superficial to the veins. The vessels leading from this plexus, four or five in number, pass upward in company with the ovarian vessels and end in the lateral aortic glands. Above the fifth lumbar vertebra these vessels anastomose with the lymphatics from the fundus of the uterus and Fallopian tube. Quite often there is a lymph-vessel which emerges from the ovary, passes downward and outward and ends in the middle chain of the internal iliac glands.

The Lymphatic Vessels of the Vagina.—The lymphatics of the vagina are divided into those of the mucous coat and those of the muscular coat; these anastomose freely with each other and terminate in a peri-vaginal network, which is drained by three groups of trunks. One group drains the upper third of the vagina and passes to the middle chain of the external iliac glands. A second group is efferent to the middle third of the vagina and ends in the hypogastric glands. A third group carries the lymph from the lower third of the vagina to the gland of the promontory.

The Lymphatic Vessels of the Testicle.—The lymphatic vessels of the testicle consist of two sets, superficial and deep; the former commence on the visceral surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the juxta-aortic and sometimes also in the pre-aortic glands; hence the enlargement of these glands in malignant disease of the testis.

The Lymphatic Vessels of the Vas Deferens.—These lymphatics empty into the external iliac glands.

The Lymphatic Vessels of the Seminal Vessicles.—A network exists on the surface of each vesicle, formed by a collection of lymph-vessels from the mucous lining and from the muscular structure of the vesicle. The trunks from this network empty into the external and internal iliac glands.

The Lymphatic Vessels of the Kidney, Ureter, and Suprarenal Capsule.—Their courses and terminations differ on the two sides. They take origin from a superficial network just beneath the capsule of the kidney and a deep network in the interior of the organ. The superficial network is connected to the collecting vessels of the deep network at the hilum. From the superficial network numerous vessels penetrate the capsule of the kidney and join the lymphatics of the fatty capsule. According to Poirier, Cunéo, and Delamare;  anterior and posterior trunks come off from the deep lymphatics of the right kidney. The anterior trunk usually terminates in the right juxta-aortic glands which lie upon the vena cava. The posterior trunks terminate in the juxta-aortic glands which lie behind the vena cava. On the left side all the collecting trunks terminate in the juxta-aortic glands of the left side of the aorta.

The lymphatics of the fatty capsule of the kidney communicate with the lymphatics of the kidney, and both terminate in the same glands. The lymphatics of the suprarenal capsule terminate in the juxta-aortic glands of the same side. From

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
the ureter lymph-vessels come off and terminate in the juxta-aortic and adjacent glands.

The Lymphatic Vessels of the Liver.—The lymphatic vessels of the liver are divisible into two sets, superficial and deep. The former arise in the lobules at the periphery of the liver and pass to the subperitoneal connective tissue over the entire organ. The latter arise from the deeper lobules, and emerge from the liver along the portal vein or the hepatic veins.

According to Poirier, Cunéo, and Delamare, three groups of superficial collecting trunks arise from the subperitoneal network. The posterior trunks divide into three groups. The single right posterior trunk terminates in a gland about the celiac axis. The middle posterior trunks (five to seven in number) pass through the opening in the Diaphragm. The left posterior trunks pass into glands about the subdiaphragmatic portion of the oesophagus. The anterior collecting trunks terminate in the lymph-glands of the hilum of the liver. The superior trunks ascend. One of these trunks or a posterior trunk passes with the vena cava through the Diaphragm and terminates in glands about the vena cava. Another trunk, an anterior one, passes over the anterior border of the liver, runs for a time with the round ligament, and terminates in the hepatic glands. Numerous middle trunks ascend in the suspensory ligament, unite beneath the Diaphragm into a short trunk of large size, which passes through the Diaphragm and divides into several smaller ducts, which terminate in the glands back of the xiphoide cartilage. Trunks from the superficial lymphatic network also emerge from the inferior surface of the liver. The posterior trunks from the right lobe reach the vena cava and terminate in the glands about the intra-thoracic end of that vessel. The middle and anterior trunks from the right lobe reach the glands along the cystic duct. The trunks from the left lobe terminate in the glands along the hepatic artery. The trunks from the lobus Spigelli reach the glands of the hilum and the glands about the lower intra-thoracic portion of the vena cava. The trunks from the quadrate lobe terminate in the glands of the hilum. The deep collecting trunks

---

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
are divisible into two groups. One group descends along the portal vein, the other ascends along the hepatic veins.

Sappey pointed out that the deep descending trunks accompany the bile pass-
eges and the branches of the portal vein, several anastomosing vessels accom-
pnanying each branch of the portal vein. The same authority affirmed that from fifteen to eighteen trunks emerge from the hilum and terminate in the adjacent glands. The deep ascending trunks surround as a sheath the branches of the hepatic vein (Sappey). As they approach the Diaphragm they diminish in num-
ber to five or six, pass through the opening for the vena cava, and terminate in the glands about the lower portion of the intra-thoracic cava.

The Lymphatic Vessels of the Bile-ducts.—The lymphatics of the bile-ducts arise from the mucous membrane and from within the muscular tissue, and terminate in glands along the cystic and common ducts.

The Lymphatic Vessels of the Stomach (Figs. 507 and 508).—The lymphatic vessels of the stomach consist of two sets, superficial and deep. The superficial arise from the outer (serous) and the middle (muscular) coats. The deep arise from the mucous membrane and form a network in the submucous tissue. Trunks from the submucous network pass through the muscular tunic and terminate in the trunks coming from the sero-muscular layers. These latter, the musculo-serous

collecting trunks, are divided into three groups. The first group is composed of six or eight vessels which pass toward the lesser curvature (Sappey). There are from three to ten glands upon the lesser curvature along the course of the gastric artery which receive these superior trunks. Vessels come to these glands from the cardia, from the body of the stomach, and from the pyloric end. In the lesser curvature the lymphatic vessels lie in the wall of the stomach. According to Cunéo, two-
thirds of the stomach is drained by the lymph-vessels of group I. The second group comprises the trunks from the greater curvature which end in the subpyloric glands. The glands along the greater curvature are some distance from the stomach wall in the pyloric region, and lymph-streams flow from left to right, that is, toward the pylorus and not from it. These lymphatics drain one-third of the stomach. The first and second groups send lymph eventually to the coeliac glands and juxta-aortic glands. The third group comprises trunks which come from the fundus of the stomach and enter the lymphatic glands about the spleen.

Surgical Anatomy.—Mikulicz pointed out the early infection of the glands of the lesser curva-
ture in pyloric cancer, and insisted that in operation for pyloric cancer the entire lesser curvature must be removed. Cunéo showed us that in pyloric cancer the fundus and two-thirds of the greater curvature usually remain free from disease, because the lymph-current is toward the pylorus and not from it. Of course, if the lymphatics become blocked, the lymph-current may be reversed (regurgitation), and then infection of these parts can occur. William J. Mayo has noted the "lymphatic isolation" of the dome of the stomach. In operating for cancer of the

Fig. 507.—Lymphatic areas of the stomach. (Cunéo.)
pylorus, make the section of the stomach as directed by Hartmann, that is, a section which removes all of the lesser curvature and cuts the greater curvature well to the left of the subpyloric glands.

The Lymphatic Vessels of the Pancreas.—The lymphatics of the pancreas arise from a network about the pancreatic lobules. The collecting trunks anastomose freely on the surface of the pancreas. Some of the trunks terminate in the splenic glands, which send vessels to the celiac glands. Others terminate directly in the celiac glands. The lymphatics of the head of the pancreas communicate with the duodenal lymphatics and the lymphatics of the lower end of the common duct. The pancreatic and splenic lymphatics probably communicate.

The Lymphatic Vessels of the Spleen.—The lymphatics of the spleen consist of two sets, superficial and deep; the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the blood-vessels, passing through a series of small glands, and pass into the splenic glands which are placed in the omentum between the spleen and pancreas. The gastro-splenic omentum contains no glands.

THE LYMPHATIC SYSTEM OF THE INTESTINES.

The Lymphatic Glands of the Small Intestine (Fig. 509).—The lymphatic glands of the small intestine are placed between the layers of the mesentery, and are called mesentery glands (lymphoglandulae mesentericae). They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small

Fig. 508.—General view of the subperitoneal lymphatic plexus of the stomach prepared by the method of Gerota. (Cunéo.)
These glands are most numerous and largest above, the glands of the jejunum being more numerous than those of the ileum. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines. The glands diminish in number as we descend until the ileo-ccecal region is reached, when a number of glands appear about the ileo-ccecal artery. The mesenteric glands receive the lacteals and send out trunks to the receptaculum chyli. The chyle from the intestine passes through the glands on its way to the thoracic duct.

The glands may be divided into: I. A group of glands the members of which are chiefly found along the terminal vessels from the vascular loops of the intestinal branches of the superior mesenteric artery. Some glands of this group are placed upon "the anterior surface of the upper end of the jejunum." II. A group of glands along the vascular loops of the superior mesenteric artery. Most of them are between the primary loops. Some of them are between the secondary and tertiary loops. III. A group of glands along the trunk of the superior mesenteric artery.

The Lymphatic Vessels of the Small Intestine (Fig. 509).—The lymphatic vessels of the small intestine are called lacteals, from the milk-white fluid they usually contain. They take origin in the intestinal villi and in lymphatic sinuses around the bases of the solitary glands. Lymphatic plexuses exist in the submucous tissue, the muscular coat, and the subserous tissue. The lymphatic vessels pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate separately in the receptaculum chyli; frequently, however, they first unite to form a single large trunk, termed the intestinal lymphatic trunk (Figs. 483, 484, and 511).

The Lymphatic Glands of the Large Intestine.—The lymphatic glands of the large intestine are divided into the colic glands and rectal glands.

The Colic Glands (lymphoglandulae coli).—The colic glands are subdivided into: 1. The ileo-colic or ileo-ccecal glands (Fig. 510), which lie along the course of the ileo-colic artery, one or two of the glands being placed upon the anterior surface of the cecum. The mesoappendix also contains a gland which com-

1 Leaf (Surgical Anatomy of the Lymphatic Glands) says it is very common to find not more than forty or fifty.

municates with glands in the mesocolon, and receives lymph from the appendix and, in the female, from the ovary. 2. Glands in the mesocolon along the right colic artery, which receive lymph from the ascending colon and the hepatic flexure. 3. Glands in the mesocolon along the middle colic artery, which receive lymph from the hepatic flexure and transverse colon. 4. Glands in the mesocolon along the left colic artery, which receive lymph from the descending colon and sigmoid flexure. The vessels from the colic glands pass to the pre-aortic glands.

The Rectal Glands.—The rectal glands lie in the mesorectum; they receive lymph from the anus and rectum and it passes from them to the lumbar and sacral glands.

The Lymphatic Vessels of the Large Intestine.—The lymphatic vessels of the large intestine consist of three sets: those of the cæcum, ascending and transverse colon, which, after passing through their proper glands, enter the mesenteric glands; those of the descending colon and sigmoid flexure, which pass to the lumbar glands, and those of the rectum and anus, which pass to the sacral and superficial inguinal glands.

Lymphatics of the Anus and Rectum.—These vessels take origin from two networks, one from the skin and mucous membrane and the other from the muscular coat. The lymph-vessels from the skin at the anal margin pass to the superficial inguinal glands. Some vessels from the skin of the anus ascend and reach the submucous plexus of the rectum, from which region lymph-vessels pass to the rectal glands, to the glands along the middle haemorrhoidal artery, and along the inferior haemorrhoidal artery, and to a pelvic gland near the origin of the internal pudic artery.1 The vessels from the anal mucous membrane and from the muscular wall of the rectum penetrate the muscular wall of the rectum with the arteries and reach the rectal glands.

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
THE LYMPHATICS OF THE THORAX.

The thoracic lymphatics are divided into the deep lymphatics of the chest wall, the diaphragmatic lymphatics, and the visceral lymphatics.

The Lymphatic Glands of the Thoracic Wall or the Parietal Lymphatics.

The lymphatic glands of the thoracic wall include the internal mammary and intercostal glands.

The Internal Mammary Glands.—The internal mammary, retro-sternal, or sternal glands form a chain of five or six glands on each side of the sternum along the course of the corresponding internal mammary artery, and back of the internal intercostal muscles. The glands are separated from the pleura by cellular tissue. The internal mammary glands receive vessels from the diaphragmatic glands, the abdominal muscles above the umbilicus, the anterior ends of the intercostal spaces, the skin over the sternum, and the mammary gland. The vessels given off by each chain form a single trunk. On the right side this trunk terminates at the junction of the internal jugular and subclavian veins, unites with the subclavian lymph-trunk to form the right lymphatic duct, or empties directly into the subclavian trunk (Fig. 486). On the left side it empties either at the junction of the subclavian and internal jugular veins or into the thoracic duct.

The Intercostal Glands (lymphoglandulae intercostales) (Fig. 511).—The intercostal glands are small glands lying in the intercostal spaces along the intercostal arteries. In the posterior end of each space they are constantly found. These are called the posterior glands, and there are one, two, or three in each space. These glands are opposite the neck of the rib or over the articulation of the rib with the vertebra. The pleura is in front of them, and they lie upon the external intercostal muscles. In the middle of the intercostal spaces are inconstant glands which are called lateral glands. They are merely interrupting nodes in the trunks from the intercostal muscles. The intercostal glands receive vessels from the intercostal muscles and pleura. They send vessels back toward the spine, which unite with lymphatics from the back part of the thorax and spinal canal, and which pass down the spine and terminate in the thoracic duct.

The Diaphragmatic Lymphatics.—The diaphragmatic lymph-glands are distinct and numerous. These glands are on the convex surface of the Diaphragm and are divided into an anterior, a middle, and a posterior group. They receive vessels from the Diaphragm and liver and send vessels to the internal mammary and posterior mediastinal glands. The lymph-vessels of the Diaphragm take origin from a capillary network contained in the spaces between the muscular and tendinous fasciculi of the Diaphragm. Numerous lymph-vessels descend until they reach the subperitoneal tissues and then ascend. Others immediately ascend to beneath the pleura. The collecting trunks are all on the convex surface of the Diaphragm. The lymphatic vessels of the Diaphragm anastomose with the lymphatic vessels of the pleura and the peritoneum. This subperitoneal network is so extensive that absorption in this region is extremely rapid. Hence, after an abdominal operation, if salt solution has been left in the abdomen, it will be very rapidly absorbed if the foot of the bed is elevated. Influenced by the knowledge that the pelvic peritoneum absorbs comparatively slowly and the peritoneum in the upper abdomen very rapidly, and that septic processes in the upper abdomen are more rapidly fatal than septic processes in the pelvis, Fowler was led to recommend the elevation of the head of the bed after operations for abdominal infections. This posture causes poisonous fluids to gravitate away from the Diaphragm.
The Visceral Lymphatics.—The visceral lymphatics include the anterior mediastinal glands, the posterior mediastinal glands, and the peritracheo-bronchial glands.

The Anterior Mediastinal Glands (lymphoglandulae mediastinales anteriores).—The anterior mediastinal glands are in the upper portion of the anterior mediastinum, a group of six or seven glands lying above and upon the front of the transverse portion of the arch of the aorta and sending glandular chains toward the neck. On the right side these glands are found between the innominate artery and vein and in front of the vein. On the left side they are in front of and behind the left common carotid and left subclavian arteries. They receive lymph from the heart, pericardium, thymus gland, and anterior mediastinum.
The Posterior Mediastinal Glands (lymphoglandulae mediastinales posteriores) (Fig. 511).—The posterior mediastinal glands are behind the pericardium and in front of the oesophagus. Occasionally one or two are placed back of the oesophagus. They receive vessels from the intercostal glands, aortic glands, deep cervical glands, and pleura, and send vessels to the thoracic duct.

The Peritracheo-bronchial Glands.—The peritracheo-bronchial glands are divided by Barety into four groups. One group is in the angle formed by the junction of the trachea and right bronchus. Another group is in a corresponding situation on the left side. Another group is below the tracheal bifurcation. The glands of the fourth group are about the points of division of the larger bronchi. The peritracheo-bronchial glands receive lymph-vessels from the lung, heart, pericardium, oesophagus, trachea, and thymus.

In infancy these glands present the same appearance as the lymphatic glands in other situations. In early adult life they assume a brownish tinge, and in old age become deep black, because they arrest particles of carbon brought from the bronchi. This change is known as anthracosis, and the darkened glands are usually sclerotic. In fact, in old age these glands often lose all lymphatic characters and become fibrous masses. These glands enlarge from infection, and when very large may compress the bronchi, the pulmonary artery, etc. They are often the seat of tuberculous deposits.

The Lymphatic Vessels of the Thoracic Wall.—The lymphatic vessels of the thoracic wall include the deep lymphatic vessels, intercostal and internal mammary, which have been described, the cutaneous lymphatics, and the lymphatics of the mammary gland.

The Cutaneous Lymphatics (Fig. 497).—The area drained by these lymphatics is very extensive. It is divided by Poirier, Cunéo, and Delamare into three regions. The anterior region extends from over the middle of the sternum to the anterior axillary line. The trunks pass to the axilla and terminate in the thoracic chain of the axillary glands. From this anterior region some accessory trunks pass above the clavicle and reach the supra-clavicular glands, and trunks may arise to one side of the mid-sternal line and pass to the opposite axilla. From the lateral region the trunks ascend to the thoracic chain of axillary glands. This region is between the anterior and posterior axillary lines. The posterior region is back of the posterior axillary line, and includes the thorax to the mid-line, and the posterior portion of the root of the neck. The trunks from the posterior area empty into the scapular group of axillary glands.

Lymphatics of the Mammary Gland (Figs. 496 and 512).—There are two sets of lymphatics in this gland, the cutaneous or superficial and the glandular or deep.

The Peripheral Cutaneous Lymphatics of the Mammary Gland.—The peripheral cutaneous lymphatics do not arise from the nipple. Their collecting trunks are arranged as are other collecting trunks of the anterior portion of the thorax, and end in the thoracic group of axillary glands of the same side. Trunks arising from the sternal margin of the skin of the breast may run to the glands of the opposite axilla.

The Central Deep Lymphatics of the Mammary Gland.—The central lymphatics form a very extensive network in the nipple and areola, and from this network numerous vessels pass into a plexus beneath the areola, Sappey's subareolar plexus; most of the trunks coming from the gland also enter the subareolar plexus.

The Glandular Lymphatics of the Mammary Gland.—The glandular lymphatics arise from spaces about the lobules and from networks about the milk-duets. We can distinguish a chief lymphatic channel and three accessory channels. The chief lymphatic channel takes origin from collecting trunks which begin in the spaces about the lobules and in the lymph-capillaries about the milk-duets. These collectors pass toward the nipple and terminate in the subareolar plexus, which plexus also receives the vessels from the areola and nipple. Two large
trunks take origin from the subareolar plexus: one from its inner side, the other from its outer side. "The internal trunk runs at first downward and then outward, turning round the inferior border of the subareolar plexus. It is thus directed toward the axilla and runs in the subcutaneous cellular tissue, along the lower border of the Pectoralis major, which it crosses at the level of the third rib to reach the base of the axilla. This collecting trunk constantly receives as afferents one or two fair-sized trunks coming directly from the inferior portion of the mammary gland. The external trunk, which is usually smaller than the preceding, runs directly outward toward the axilla. Before it reaches the latter it is augmented by a vessel coming from the superior part of the gland. At the base of the axilla these two collecting trunks perforate the axillary aponeurosis and terminate in one or two glands, placed on the inner wall of the axilla on the third digitation of the Serratus magnus muscle. These glands (the principal regional glands of the breast) may or may not be covered by the lower part of the Pecto-

---

Fig. 512.—The vessels and lymphatics of the anterior face of the mammary glands. (Sappey.)

The Lymphatics of the Thoracic Wall

are usually interrupting glands along this channel, the retro-pectoral glands. The subclavian channel runs along the superior thoracic artery. They call the third accessory channel the internal mammary channel. The collecting trunks arise from the inner portion of the mammary gland and pass along the vessels sent off from the internal mammary artery to the gland. They pierce the Pectoral and Intercostal muscles and reach the internal mammary glands. This channel is constant and along it there may be interrupting glands.

**Lymphatics of the Great Pectoral Muscle.**—The lymphatics of the great Pectoral muscle end in the subclavian glands, the thoracic group of axillary glands, and the internal mammary glands.

**Surgical Anatomy.**—A knowledge of the lymphatics of the breast and of the glands into which the lymphatics drain is of the first importance to a surgeon. Certain surgical deductions from the anatomy of this region are perfectly obvious—viz.: 1. If the skin of the mammary gland is involved in carcinoma, the thoracic group of axillary glands of the same side is involved. If the skin over the sternal margin of the gland is involved, the glands of the opposite axilla may be cancerous, as from this point lymph-vessels rise and pass across the mid-line. If the skin of the sternal margin is involved the prognosis is worse than if it is free, the opposite axilla may be cancerous, and the opposite breast may become diseased. 2. When lymphatic ducts become blocked by cancer cells the lymph backs up, flows backward instead of in its proper direction, and may cause infection in the most unsuspected situations. For instance, a block in the cutaneous lymphatics of a portion of the breast may lead to infection of the opposite breast and axilla, though, of course, it is not so likely to as is cancer of the skin of the sternal margin. By regurgitation of lymph the head of the humerus or the retro-ternal structures may become diseased in mammary cancer. 3. If the nipple or areola is cancerous, the entire gland is sure to be diseased, as the lymphatic network of this region empties into the subareolar plexus, and most of the trunks coming from the gland also enter this plexus. 4. If the mammary gland is cancerous, all of the axillary glands are regarded as diseased, as the main lymphatic channel from the breast reaches the glands on the inner wall of the axilla upon the third digitation of the Sternotus magnus. Furthermore, in many cases an accessory lymph-channel comes off from the lower portion of the mammary gland and passes directly to the axilla. 5. The subclavian glands are to be regarded as diseased, because in a certain proportion of cases (the exact proportion being uncertain) an accessory lymph-channel comes off from the posterior surface of the mammary gland, passes through the great Pectoral muscle and ascends between the greater and lesser Pectorals to reach the subclavian glands. 6. The element which greatly interferes with the cure of mammary carcinoma is the existence of lymph-channels which arise from the inner portion of the mammary gland, pierce the greater Pectoral and Internal intercostal muscles, and reach the internal mammary glands. Mediastinal involvement is apt to be earlier in carcinoma of the inner portion of the breast than in carcinoma of other portions, and the prognosis is particularly bad in cancer of the inner portion of the breast. What is known as the **stenal symptom** of Snow is bulging of the sternum due to involvement of the thymus gland. 7. The sternal portion of the great Pectoral and the tissue between it and the lesser Pectoral muscle are to be regarded as diseased, because in some cases an accessory lymph-channel from the breast penetrates the greater Pectoral and ascends to the subclavian glands. This trunk has several interrupting or satellite glands, the retro-pectoral glands, in the tissue back of the great Pectoral muscle. 8. When the great Pectoral muscle is diseased, cancer cells soon spread widely through the sternal portion of the muscle, and this entire portion of the muscle becomes cancerous. The clavicular portion does not suffer early, but escapes until the cancer becomes extensive, as it is anatomically distinct from the sternal portion. If the fibres of the great Pectoral are extensively diseased, the thoracic group of axillary glands, the subclavian glands, and possibly the internal mammary glands are involved. 9. The only operation in cancer of the breast which offers any real hope of cure is one which is done early and is radical. 10. It must be done early, because delay permits involvement of the mediastinum, and if the disease has entered the mediastinum operation is hopeless. If the sternum is bulged operation is useless, and nothing short of amputation at the shoulder-joint could be of help if the head of the humerus is enlarged by the disease. Even this radical procedure is of no avail, because the mediastinum is certainly involved if the head of the humerus is diseased. 11. If the lymph-glands above the clavicle are extensively diseased operation is useless, as in such cases the mediastinum is sure to be involved. 12. A radical operation means the removal of the skin of the breast with the nipple and areola, the subcutaneous tissue of this region, the entire breast the sternal portion of the great Pectoral with its fascia, the retro-pectoral glands and tissue, all the contents of the axilla except vessels and nerves, the glands and cellular tissue beneath the anterior margin of the Latissimus dorsi, and the subclavian glands. It is probably always wisest to open above the clavicle as well as below to facilitate the removal of glands. It is seldom necessary
to remove the clavicular portion of the greater Pectoral. The lesser Pectoral does not require removal, but it should be taken away, because of the added safety and speed thus obtained in cleaning the great vessels and because its retention does not improve the functional result. The surgeon must remember that the breast is a much larger organ than we used to think, and all of its irregular projections and outlying lobules must be removed (p. 793). Formerly, surgeons did not completely remove the breast, but only got rid of a large portion of it.

The Pulmonary Lymphatics.—The pulmonary lymphatics arise from networks between the lobules, around the bronchi and under the mucous membrane. The collecting trunks are in two sets, superficial and deep: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi; they both terminate at the root of the lungs in the tracheo-bronchial glands.

The Pleural Lymphatics.—The lymphatics of the pulmonary pleura pass into the superficial pulmonary trunks; those from the costal pleura enter the intercostal trunks; those from the diaphragmatic pleura enter the diaphragmatic trunks, and those from the mediastinal pleura enter the posterior mediastinal glands.¹

The Cardiac Lymphatic Vessels.—The cardiac lymphatic vessels consist of two sets, superficial and deep: the former arise in the subpericardial areolar tissue of the surface, and the latter in the subendocardial tissue. From the network of deep lymphatics trunks pass to the superficial lymphatics. The superficial lymphatics follow the course of the coronary vessels. Two trunks are formed: an anterior, which lies in the anterior interventricular furrow, and an inferior, which lies in the inferior interventricular furrow. These two trunks collect the lymph from the ventricles and pass to the base of the heart, where they receive lymph from the auricles. The anterior or left trunk ascends between the left auricle and the pulmonary artery on the posterior surface of the artery, perforates the pericardium, and enters the glands about the tracheal bifurcation. The right, posterior or inferior trunk ascends between the aorta and pulmonary artery and terminates in the same group of glands as the left trunk.

The Thymic Lymphatic Vessels.—The thymic lymphatic vessels arise from the under surface of the thymus gland, and enter the anterior mediastinal, the internal mammary, and the peritracheo-bronchial glands.

The Lymphatic Vessels of the Oesophagus.—The lymphatics of the thoracic oesophagus arise from two networks, one beneath the mucous membrane and one beneath the muscular fasciculi. The connecting trunks terminate in the perioesophageal glands.

The Lymphatic Vessels of the Thoracic Trachea.—The lymphatics of the thoracic trachea take origin from a network in the submucous tissue. From this a number of collecting trunks pass through the trachea in the line of junction of the cartilaginous with the membranous portion. They terminate the peritracheo-bronchial glands.

THE NERVOUS SYSTEM.

THE nervous system consists of (1) the cerebro-spinal nervous system and (2) the sympathetic nervous system.

1. The Cerebro-spinal Nervous System is composed of the spinal cord and brain and of nerves joined to the brain and cord. The spinal cord and brain constitute the cerebro-spinal axis, or, as it is also called, the encephalo-spinal axis, the neuraxis, or the central nervous system. The nerves which join the cord and which join the brain constitute the peripheral nervous system. The term central nervous system is applied to structures contained altogether within the spinal and cranial cavities, but this narrow use is not strictly accurate. By far the greater part of the central nervous system is contained within those cavities, but any centre of energy must be regarded as a portion of the central system, and certain ganglia which are centres of energy lie along certain nerves and really belong to the central nervous system, though they are discussed with the peripheral nerves.

The term peripheral nervous system does not mean, as it would seem to, structures outside the spinal and cranial cavities. The chief part of the peripheral system is outside of the spinal and cerebral cavities, but peripheral nerves "sometimes run a considerable distance within these cavities." The peripheral nervous system is composed of thirty-one pairs of spinal nerves and twelve pairs of cranial nerves. Each spinal nerve is joined to the spinal cord by two roots, an anterior and a posterior root, and the posterior root at one point has an enlargement called a spinal ganglion. The fifth cranial nerve, alone among cranial nerves, takes origin by two roots, as does a spinal nerve. Five of the cranial nerves possess ganglia similar to the ganglia on the posterior roots of the spinal nerves. The cranial nerves which possess ganglia are the trigeminal or fifth, the facial or seventh, the auditory or eighth, the glosso-pharyngeal or ninth, and the pneumogastric or tenth.

2. The Sympathetic Nervous System consists of a chain of ganglia on either side of the vertebral column. The ganglia of each chain are joined by cords of nervous matter. The sympathetic system contains, beside the gangliated cords, numerous nerve plexuses and ganglia in various regions. The sympathetic nervous system is closely connected at many points with the cerebro-spinal nervous system, and the two systems in all probability develop from a common origin.

Structure of the Cerebro-spinal Nervous System.—The spinal cord and brain contain gray matter and white matter. The gray matter is vascular and is composed chiefly of nerve-cells: the white matter is less vascular and is composed chiefly of nerve-fibres. Until recently it was the custom to regard nerve-cells and nerve-fibres as definitely distinct elements, but we now know that nerve-fibres are processes of nerve-cells. One process, several processes, or many processes come off from nerve-cells. If there is but one process from a cell, that process becomes Deiters' process, the axis-cylinder or axone of a nerve-fibre. If more than one process comes off from a cell, one of the processes becomes an axone, and the other processes are known as protoplasmic or dendritic processes, or, as His named

1 The Nervous System and Its Diseases, By Charles K. Mills.
them, **dendrites**. There are no nerve-fibres unconnected with cells. The nerve-cell, with its axone and its dendrites, constitutes what is called a **nerve-unit** or **neurone**. The nervous system is said to be composed of aggregations of multitudes of neurones. The term neurone was devised by Waldeyer in 1891.

**Gray, vesicular, or cineritious substance** is of a dark, reddish-gray color and of a soft consistence. It is found in the spinal cord, brain, and various ganglia, in some of the nerves of special sense, and in gangliform enlargements in the course of certain spinal nerves. It is composed of nerve-cells and contains blood-vessels, both the cells and vessels being embedded in a ground substance named by Virchow the **neuroglia**. The nerve-fibres and the vessels in the white substance are also embedded in neuroglia. Neuroglia consists of fibres and neuroglia cells. Some of the cells are stellate in shape and their fine processes become neuroglia-fibres, which extend radially and unbranched (Fig. 513 B) among the nerve-cells and fibres, which they aid in supporting. Other cells give off fibres, which branch repeatedly (Fig. 513 A).

![Fig. 513. Neuroglia-cells of brain shown by Golgi's method. A. Cell with branched processes. B. Spider-cell with unbranched processes. (After Andriezen.) (Copied from Schäfer's Essentials of Histology.)](image)

In addition to these fibres there are others which do not appear to be connected with the neuroglia-cells. They start from the **lining ependymal cells**, that is, the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly, to terminate in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function, though it is not in development; it is epiblastic in origin, whereas all true connective tissues are mesoblastic.

The **white** or **fibrous tissue** is composed of nerve-fibres, which, with blood-vessels, are embedded in neuroglia.

**Nerve-cells or the Cell-bodies of the Neurones** (Figs. 514, 515, 516, 517, 518, and 519).—Nerve-cells constitute the essential element of nervous tissue. They are the originators of nervous impulses and impressions. All nervous conduction is from nerve-cell to nerve-cell by contact (Mills), and the transmission of an impulse from one nerve-cell to another may be over a long distance. The nerve-cells of the brain and cord differ in origin, development, and connections from the nerve-cells of the spinal ganglia. They vary greatly in shape and size (Fig. 515). Some are so small that they become visible only under a microscope of high
power; some "almost come within the range of unaided vision." The largest cells are found in the anterior cornua of the spinal cord, in the vesicular columns of Clarke, in the large pyramidal cell-layer of the cerebral cortex, and the Purkinje cell-layer of the cerebellum. The smallest cells are in the olfactory bulbs, in the substantia gelatinosa Rolandi of the cord, and in the granular cortical layers of the cerebrum and cerebellum.

The Body of the nerve-cell may possess a limiting membrane, as is seen in the cells of the spinal ganglia (Fig. 516) and sympathetic ganglia, and some of the cells of the Gasserian ganglion (Figs. 514, j and g), but may be devoid of any limiting membrane, as is seen in the motor cells of the anterior cornua of the cord (Fig. 517). All cell-bodies, like all cell-processes, show intracellular fibrillation, and the fibrils of the cell-body are continuous with those of the axone and run in

---

various directions. The cell-body is composed of protoplasm, which contains, besides fibrils, many fine spindle-shaped granules. The granules stain deeply and are called chromatophile granules, Nissl's bodies, or trigoid bodies (Fig. 517). They are probably nucleo-albumins (Held). Most nerve-cells, certainly most large nerve-cells, possess considerable pigmented material, a nucleus, and a nucleolus.

The nucleus (Fig. 514 b) is, as a rule, a large, well-defined, round, vesicular body, often presenting an intranuclear network. It contains a nucleolus (Fig. 514 e), which is peculiarly clear and brilliant. Pigment granules (Fig. 514 e), when present, lie by the side of the nucleus. Masses of pigment are present in the cells of the substantia nigra and locus ceruleus.

Nerve-cells are divided for purposes of study into three groups, according to the number of their processes.

1. **Unipolar Cells.**—The single process of such a cell, after a short course, divides in a T-shaped manner. Unipolar cells are found in the spinal ganglia of the adult and among the olfactory cells of mammals.

2. **Bipolar cells** (Fig. 516) are found in spinal ganglion-cells when the cells are in an embryonic condition. They are best demonstrated in the sympathetic ganglion-cells of a frog. Sometimes the processes come off from opposite poles of the cell, and the cell then assumes a spindle shape; in others they both emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around the ganglion-cell, or, again, it may be coiled spirally around the nerve-process which is issuing from the cell.
3. **Multipolar cells** (Fig. 517) are caudate or stellate in shape, and are characterized by their large size and by the tail-like processes which issue from them. The processes are of two kinds: one of them is the axis-cylinder or axone; the others are the protoplasmic processes or dendrites.

**The Axone** (Figs. 515, 516, 517, 518, and 519).—The axone emerges from the nerve-cell by a slender stalk; it is smooth and free from Nissl's bodies; it maintains a uniform diameter for a considerable distance; it does not, as a rule, divide into branches, although it may possess collaterals, and it becomes the axis-cylinder of a nerve-fiber. Cerebro-spinal axones, as a rule, are medullated, except near their terminations. Sympathetic axones are non-medullated. Axones may be extremely short or may be several feet in length. The fibres of the pyramidal tract are axones of great length. Some short axones divide at their terminations into many branches. Short axones are called **dendraxones**, and the cells with dendraxones are called the **second type of Golgi cells**. An axone may remain throughout its entire course in the brain or cord or may enter into a spinal or cerebral nerve. Most cells possess but one axone, and such a neurone is called **monoaxonic**. A cell may possess two axones, the neurone being called **diagonal**, or several axones, the neurone being called **polyaxonic**. The **collaterals** are branches given off from the neurone at right angles to it. Some axones have a number of collaterals; others do not have any. They are present everywhere in the central nervous system (Cajal, Kölliker). Some collaterals are medullated; others are not. They approach the dendrites of the nerve-cells of the neurones. Each axone and collateral ends in a button-like termination or **end-tuft**, or in a free arborization, the **end-brush**. If the termination is within the brain or cord, it may wrap around nerve-cells or arborize about dendrites. If the axone emerges from the cerebrospinal axis, it terminates about muscle-cell or some other structure. The termination of the axone or the collateral is never continued into the structure about which it lies. It may surround that tissue; it may touch it; it may lie close against it, but the termination is free, and the relation is simply one of contact and not of continuity.

**The Dendrites.**—The dendrites are protoplasmic processes resembling in structure and staining reactions the protoplasm of the body of the cell. Each emerges by a thick base (gemmule), and divides into many fine branches, with free ends. They are not straight, are not smooth, and do not maintain the same diameter for a considerable distance as does the axis-cylinder. A dendrite may branch at any distance from the body of the cell, and the branches do not join. The dendrites from a single cell vary greatly in number, thickness, and length. Some cells are devoid of dendrites; some give off a few; some give off many. As a rule, they are non-medullated.

**The Theory of Neurones.**—This theory maintains that the nervous system is composed of a multitude of units called neureones. Each neurone consists of a cell and processes. The neurones in aggregation form cell groups and fibre systems. The connection of nerve-cells with other nerve-cells is not by continuity of structure. It is by contact and not by actual junction; it is physiological and not anatomical. "When fully developed in man, perhaps a very small number of neurones are united together by concrescence or protoplasmic bridges, but their predominant relation is certainly that of contact or synapse." Process comes in contact with process, or process with cell. The terminal tufts of the axone of a cortical motor-cell surround a cell in the anterior horn of the spinal cord, and this spinal cell sends out an axone, the termination of which reaches a muscle. Doubt has of late arisen as to the neurone theory, because of the investigations of Apáthy and others. Apáthy claims that ganglion cells join directly and that the ultimate

---

1 Anatomy of the Brain and Nervous System. By Harris E. Santee.
elements of the nervous system are neurofibrils, which pass from cell to cell. However, as stated by Szymonowicz,\(^1\) Apáthy’s observations, even if correct, do not disprove the neurone theory, but indicate that the nervous units or neurones are occasionally connected by neurofibrils.

**Nerve-fibres.**—Nerve-fibres serve to conduct nervous impulses and bring nerve-cells into relation with each other and into relation with other structures. Nerves are composed of numbers of nerve-fibres bound into bundles. There are two sorts of fibres: medullated or white and non-medullated or gray.

The Medullated fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and gives to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts (Figs. 520 and 521). The central portion is named the axis-cylinder of Purkinje (Fig. 521); around this is a sort of sheath of fatty material, staining black with osmic acid, named the white substance of Schwann (Fig. 521), which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the neurilemma, primitive sheath, or nucleated sheath of Schwann (Fig. 521).

The axis-cylinder is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-tube, the whole substance being greater in proportion in the nerves than in the central organs. It is perfectly transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride (Fig. 521). At its termination the axis-cylinder of a nerve-fibre may be seen to break up into fibrillæ, confirming the accepted view of its structure. These fibrillæ have been termed the primitive fibrillæ of Schultze. The axis-cylinder is said

---

1 Text-book of Histology and Microscopic Anatomy. By Dr. Lasius Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.
by some to be enveloped in a special, reticular sheath, which separates it from the white matter of Schwann, and is composed of a substance called neurokeratin. The more common opinion is that this network or reticulum is contained in the white matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to demonstrate it. The medullary sheath or white substance of Schwann (Fig. 521) is regarded as being fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. The white matter varies in thickness to a very considerable extent, in some nerve-fibres forming a layer of extreme thinness, so as to be scarcely distinguishable; in others forming about one-half of the nerve-tube. The size of the nerve-fibres, which varies from \( \frac{1}{2000} \) to \( \frac{1}{20000} \) of an inch, depends mainly upon the amount of the white substance, though the axis-cylinder also varies in size within certain limits. The white substance of Schwann does not always form a continuous sheath for the axis-cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These constrictions were first described by Ranvier, and are known as the nodes of Ranvier (Fig. 522). The portion of nerve-fibre between two nodes is called an internodal segment. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. In addition to these interruptions oblique clefts may be seen in the medullary sheath, subdividing it into irregular portions, which are termed medullary segments or segments of Lantermann (Fig. 521). There is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance; this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of certain reagents.

The neurilemma or primitive sheath, sometimes called the tubular membrane or sheath of Schwann (Fig. 521), presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve-fibres, being absent in those fibres which are found in the brain and spinal cord.

Non-medullated Fibres.—Most of the nerves of the sympathetic system, and some of the cerebro-spinal, consist of another variety of nervous fibres, which are called the gray or gelatinous nerve-fibres—fibres of Remak (Fig. 523). These consist of a central core or axis-cylinder enclosed in a nucleiated sheath, which tends to split into fibrillae, and is probably of the nature of neurokeratin. In external appearance the gelatinous nerves are semi-transparent and gray or yellowish-gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

Development of Nerve-cells and Fibres.—The nerve-cells are developed from certain of the cells which line the neural canal and form the neural crest of the embryo. Some of these cells assume a rounded form and are termed neuroblasts,
and from each neuroblast there grows out a process, the axis-cylinder process or axone, and subsequently the branching processes or dendrons. The axis-cylinders, at first naked, acquire their medullary sheaths, possibly by some metamorphosis of their outer layer. The neurilemma is thought to be derived from mesoblastic cells which become flattened and wrapped around the fibre, the cement-substance at their opposed ends forming the material which stains with silver nitrate at the nodes of Ranvier. Nerve-cells in the sympathetic and peripheral ganglia take their origin from small collections of neuroblasts, which are split off from the rudimentary spinal ganglia. Cells which are, originally, similar to neuroblasts seem to give rise to neuroglia-cells, numerous processes sprouting from the cell to form the neuroglial fibres.

Chemical Composition.—The amount of water in nervous tissue varies with the situation. Thus in the gray matter of the cerebrum it constitutes about 83 per cent., in the white matter from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent. The solids consist of proteids (in the gray matter proteids constitute half the total solids), neurokeratin, nuclein, protacon, lecithin, cerebro-

![Fig. 523.-A small nervous branch from the sympathetic of a mammal. a. Two medullated nerve-fibres among a number of gray nerve-fibres, b.](image)

![Fig. 524.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters. The medullated fibres are seen as circles with a central dot—viz., medullary sheath and axis-cylinder—in transverse section. They are embedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. p. Perineurium, consisting of laminas of fibrous connective tissues, alternating with flattened nucleated connective-tissue cells. L. Lymph-space between epineurium and surface of nerve-bundle. (Klein and Noble Smith.)](image)

sides, cholesterin, nitrogenous extractives, and salts, with some gelatin and fat from the adherent connective tissue.

The nervous structures are divided, as before mentioned, into two great systems—viz., the cerebro-spinal, comprising the spinal cord and brain, the nerves connected with these structures and the ganglia situated on them; and the sympathetic, consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration; they are composed of the two kinds of nervous tissue above described, intermingled in various proportions, and having, in some parts, a very intricate arrangement.

The nerves are round or flattened cords, formed of a number of nerve-fibres. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the cerebro-spinal, which proceed from the cerebro-spinal axis, and the sympathetic or ganglionic nerves, which proceed from the ganglia of the sympathetic. The cerebro-spinal nerves consist of numerous
nerve-fibres collected together and enclosed in a membranous sheath (Fig. 524). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a **funiculus**: if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or fasciculi, which are bound together in a common membranous investment.

In structure the common membranous investment, or **sheath** of the whole nerve, which is called the **epineurium**, as well as the **septa** given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi, called the **perineurium**, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue, which has a distinctly lamellar arrangement, being composed of several lamelle, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue called the **endoneurium**. It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground-substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of medullated nerve-fibres the non-medullated existing in very small proportions.

The **blood-vessels** supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, the **vaso-motor fibres**, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain medullated fibres as running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed **nervi nervorum**, are considered by him to have an important bearing upon certain neuralgic pains.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining funiculus.

The communications which take place between two or more nerves form what is called a **plexus**. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the
individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The sympathetic nerves are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected into funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres (Fig. 523), and the amount varies in different nerves, and may be known by their color. Those branches of the sympathetic which present a well-marked gray color are composed more especially of gelatinous nerve-fibres, intermixed with a few medullated fibres; while those of a white color contain more of the latter fibres and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixtures, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey impressions of a twofold kind. The sensory nerves, called also centripetal or afferent nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The motor nerves, called also centrifugal or efferent nerves, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression "the termination of nerve-fibres" is signified their connection with the nerve-centres, and with the parts they supply. The former are sometimes called their origin, or central termination; the latter their peripheral termination. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor and the posterior sensory. The point where the nerve-root or roots emerge from the nervous centre is named the superficial or apparent origin, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the gray substance, which constitutes the deep or real origin of the nerve.

The manner in which these fibres arise at their deep origin varies with their functions. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the gray substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inward either from nerve-cells in the organs of special sense (e.g., the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre, they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Peripheral Terminations of Nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves, respectively. Sensory nerves would appear to terminate either in minute primitive fibrillae or networks of fibrillae; or else in special terminal organs, which
have been termed peripheral end-organs, and of which there are several principal varieties—viz., the end-bulbs of Krause, the tactile corpuscles of Wagner, the Pacian corpuscles, and the neuro-tendinous and neuro-muscular spindles.

Termination in Fibrillæ.—When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis-cylinder, surrounded by the neurilemma, and forming a non-medullated fibre. This, after a time, loses its neurilemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis-cylinder breaks up into its constituent primitive nerve-fibrillæ, which often present regular varicosities and anastomose with one another, thus forming a network. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and there terminating, though some observers maintain that the actual terminations are within the cells. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

![Diagram](image)

Fig. 525.—End-bulb of Krause. a. Medullated nerve-fibre. b. Capsule of corpuscle. (From Klein's Elements of Histology.)

The End-bulbs of Krause (Fig. 525) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective-tissue sheath of a medullated fibre, and containing a soft semifluid core in which the termination of the axis-cylinder is situated, ending either as a bulbous extremity, or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, where they are spheroidal in shape in man, but cylindrical in most other animals, in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the genital organs of both sexes, the penis in the male, and the clitoris in the female. In this situation they have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to six knob-like masses, and have received the name of genital corpuscles. Very similar corpuscles are found in the epineurium of nerve-trunks. In the synovial membrane of certain joints (e.g., those of the fingers) rounded or oval end-bulbs have been found; these are designated articular end-bulbs.

Tactile Corpuscles, known as Grandry’s corpuscles, have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals,
especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

Meissner's corpuscles are the tactile corpuscles (Fig. 526), described by Wagner and Meissner. They are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and imperfect membranous septa, derived from it, which penetrate its interior. The axis-cylinder of the medullated fibres passes through the capsule, and having entered the corpuscle terminates in a small globular or pyriform enlargement, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillae of the corium of the skin, hand, foot, front of the forearm, and skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillae, but from their existence in those parts in which the skin is highly sensitive, it is probable that they are especially concerned in the sense of touch, though their absence from the papillae of other tactile parts shows that they are not essential to this sense. They may be regarded as end-bulbs.

Ruffini has described a special variety of nerve-ending in the subcutaneous tissue of the human finger (Fig. 527). These are usually known as Ruffini's nerve-endings. They are principally situated at the junction of the corium with the subcutaneous tissue; they are oval in shape, and consist of a strong connective-tissue sheath, inside which the nerve-fibre divides into numerous branches, which show varicosities and end in small free knobs. They resemble the corpuscles of Golgi.

The Pacinian Corpuscles or Corpuscles of Vater (Fig. 528) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes, lying in the subcutaneous tissue; but they have also been described as connected with the nerves of the joints, and in some other situations in the lower animals, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat) consists of a number of lamellae or capsules, arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar
arrangement. Todd and Bowman have described minute arteries as entering by
the sides of the nerves and forming capillary loops in the intercapsular spaces,
and even penetrating into the central space. Other authors describe the artery as entering the
corpuscle at the pole opposite to the nerve-fibre.

Herbst has described a somewhat similar "nerve-ending" to the Pacinian corpuscle, as
being found in the mucous membrane of the tongue of the duck and in some other situations.
It differs, however, from the Pacinian corpuscles in being smaller, its capsules thinner and more
closely approximated, and especially in the fact that the axis-cylinder in the central clear space is
coated with a continuous row of nuclei. These bodies are known as the corpuscles of Herbst.

Neuro-tendinous Spindles.—The nerves supplying tendons have a special modification of the terminal
fibres, especially numerous at the point where the tendon is becoming muscular. The tendon bundles
become enlarged, and the nerve-fibres—one, two, or more in number—penetrate between the fasci-
culi of the tendon and spread out between the fibres to end in irregular disks or varicosities. A
spindle-shaped body is thus formed, composed of tendon bundles and nerve-fibres, which is known as
the organ of Golgi (Fig. 529).

Neuro-muscular Spindles.—In the majority of voluntary muscles there have been found special
end-organs consisting of a small bundle of peculiar muscular fibres (intrafusal fibres), embryonic
in type, invented by a capsule within which nerve-fibres, experimentally shown to be sensory in
origin, terminate. These neuro-muscular spindles vary in length from \( \frac{1}{36} \) to \( \frac{1}{5} \) of an inch and have a
distinctly fusiform appearance. The large medullated nerve-fibres passing to the
end-organ are from one to three or four in number; entering the fibrous capsule

they divide several times, and, losing their medulla, ultimately end in naked axis-
cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid
or rounded disks (Fig. 530). Neuro-muscular spindles have not yet been demonstrated in the tongue or eye muscles.

In the organs of special sense the nerves appear to terminate in cells which belong to the epithelial class, and have received the name of sensory or nerve-epithelium cells. This is not, however, the real state of the case; the nerve-fibre is in reality a process from the epithelial cell, and terminates by branching around a ganglion-cell. The stimulus carried by it is continued onward by an axis-cylinder, derived from the ganglion, to the brain. These nerve-epithelium cells must therefore be regarded as modified forms of nerve-cells. They will be more particularly described in connection with the description of the organs of special sense.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the unstriped or involuntary muscles the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate plexus. At the junction of the branches small triangular nuclear bodies, the ganglion-cells, are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrillæ of which the nerve is composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischler, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhausser believed that these ultimate fibrillæ penetrated the muscular cell and ended in the nucleus. More recent observation, however, has tended to disprove this.

In the striped or voluntary muscle the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve-fibre terminates in a special expansion, called by Kuhne, who first

---

**Fig. 530.**—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)
accurately described it, the **motorial end-plates** (Fig. 531).¹ The nerve-fibre, on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with the sarco-

---

¹ They had, however, previously been noticed, though not accurately described, by Doyère, who named them "nerve-hillocks."—Ed. of 15th English edition.
The ganglia are invested by a smooth and firm, closely adhering membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (Fig. 532), consisting of the same structural elements as the other nervous centres—viz., a collection of nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath, which is continuous with the sheath of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves are pyriform in shape, and have only one process, the axis-cylinder or axone. A short distance from the cell, and while still within the ganglion, this process divides in a T-shaped manner, one limb of the cross-bar passing centrally and forming the central portion of a sensory nerve-fibre; the other limb passing peripherally to form the axis-cylinder process of the peripheral nerve-fibre. In the sympathetic ganglia the nerve-cells are multipolar and have one axis-cylinder process or axone and several protoplasmic processes or dendrons. The former of these emerges from the ganglion as a non-medullated nerve-fibre. Similar cells are found in the ganglia connected with the fifth cranial nerve, and these ganglia are therefore regarded by some as the cranial portions of the sympathetic system. The nerve-cells are disposed in the ganglia in groups of varying size, and these groups are separated from each other by bundles of nerve-fibres, some of which traverse the ganglia without being connected with the cells.

**THE CEREBRO-SPINAL AXIS.**

The cerebro-spinal axis consists of the spinal cord and the brain or encephalon, which are contained within the skull and spinal canal. The spinal cord and its coverings will be first considered, and then the brain and its membranes.

**THE SPINAL CORD AND ITS MEMBRANES.**

**Dissection.**—To dissect the cord and its membranes it will be necessary to lay open the whole length of the spinal canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawed through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps.

**MEMBRANES OF THE CORD.**

The membranes which envelop the spinal cord are three in number. The most external is the dura mater, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the pia mater, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the arachnoid membrane, a non-vascular membrane which envelops the cord and is connected to the pia mater by slender filaments of connective tissue.

**The Spinal Dura Mater (Dura Mater Spinalis) (Figs. 533, 534, 535, 537).**

The spinal dura mater represents only the meningeal or supporting layer of the cranial dura mater. The endocranial or endosteal layer ceases at the foramen magnum posteriorly, but reaches as low as the third cervical vertebra in front; below these levels its place is taken by the periosteum. The dura mater forms a
loose sheath which surrounds the cord and the cauda equina, and is loosely connected with the vertebral periosteum and the ligaments by a quantity of lax areolar tissue and a plexus of veins, the **meningo-rachidian veins** (*plexus venosi vertebrales interni*). The space containing the fat and veins is called the **epidural space** (*cavum epidurale*). The situation of the veins between the dura mater and the periosteum of the vertebrae corresponds therefore to that of the cranial sinuses between the endocranial and supporting layers. The dura is attached to the circumference of the foramen magnum and to the axis and third cervical vertebra; it is also fixed to the posterior common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the second or third piece of the sacrum; here it becomes impervious, and, ensheathing the filum terminale, constitutes the **filum durae matris spinalis** (Fig. 537), and descends to the back of the coccyx, to blend with the periosteum. This part of the dura is called the **coccygeal ligament**.

(Fig. 537). The dura mater is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings, which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura mater are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the spinal canal.

The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:

The dura mater of the cord is not closely adherent to the bones of the spinal canal, and is not, as is the cerebral dura, the internal periosteum of the vertebrae. The vertebrae have an independent periosteum.
The Nervous System

It does not send partitions into the fissures of the cord, as the cerebral dura sends partitions into certain fissures of the brain.

Its fibrous laminae do not separate to form venous sinuses, as in the brain.

Structure.—The dura mater consists of white fibrous and elastic tissue arranged in bands or lamellae, which, for the most part, are parallel with one another and have a longitudinal arrangement. Each surface is covered by a layer of endothelial cells. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The Arachnoid Membrane (Arachnoidea Spinalis) (Figs. 533, 535).

The arachnoid is exposed by slitting up the dura mater and rendering that membrane to either side. It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, joined together by isolated connective-tissue trabeculae. These trabeculae are especially numerous on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the subdural space (cavum subdurale). The subdural space contains a very small amount of lymph-like fluid. There is no communication between the subdural space and the subarachnoid space. The subdural space is prolonged outward for a short distance on each emerging nerve and communicates with the lymph tract of the nerve. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the subarachnoid or subarachnoidean space (cavum subarachnoideale). The space is largest at the lower part of the spinal canal, and encloses the mass of nerves which form the cauda equina. Superiorly it is continued with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of openings in the pia mater, in the roof of the fourth ventricle, foramen of Majendie and foramina of Key and Retzius (p. 852). It contains an abundant serous secretion, the cerebro-spinal fluid (liquor cerebrospinalis). This secretion is sufficient in amount to expand the arachnoid membrane, and thus to distend completely the whole of the space included in the dura mater. The subarachnoid space is occupied by trabeculae of delicate endothelial covered connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named subarachnoid tissue.

In addition to this the space is partially subdivided by a longitudinal membranous partition, the septum posticum or the posterior fenestrated septum (septum subarachnoideale), which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure of the spinal cord. It is a partition, but an incomplete and cribriform partition, consists of bundles of white fibrous tissue interlacing with each other, and is coated with endothelium. The ligamenta denticulata, which run from the pia mater to the dura mater on either side of the cord, divide the subarachnoid space into an anterior and a posterior space (cavum subarachnoideale anterius et posterius), which join like spaces in the cavity of the cranium. The medulli-spinal veins (venae spinales externae) lie in the subarachnoid space.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers. It con-
tains many elastic fibres, and is covered on each side by endothelial cells. The arachnoid contains neither vessels or nerves.

**The Pia Mater of the Cord (Pia Mater Spinalis).**

The pia mater of the cord is exposed on the removal of the arachnoid (Figs. 533 and 535). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the *linea splendens*; and a somewhat similar band, the *ligamentum denticulatum*, is situated on each side. At the point where the cord terminates the pia mater becomes contracted, and is continued down as a long, slender filament, the *filum terminale* (Fig. 537), which descends within the sheath of the dura and the arachnoid and through the centre of the mass of nerves forming the *cauda equina*. It unites with the dura and arachnoid about the level of the third sacral vertebra, and as the *central ligament of the spinal cord*, the *coccygeal ligament*, or the *filum durae matris spinalis* the fused membranes extend downward as far as the base of the coccyx, where they blend with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk. It contains a little gray nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia mater presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

**Structure.**—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer, resembling the arachnoid, composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner (*intima pia*), consisting of stiff circular bundles of the same tissue, which present peculiar angular bends. It is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleft-like lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. The pia mater contains the *anterior spinal artery* and its branches, the two *posterior spinal arteries*, and numerous veins which pass to the medulli-spinal veins. It is also supplied with nerves, which are derived in part from the *sympathetic* and in part from the *cerebro-spinal nerves*. These nerves supply the walls of the blood-vessels and enter the cord with the vessels.

The *Dentate Ligament* (*ligamentum denticulatum*) (Figs. 533 and 534) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, running from the pia mater to the dura mater, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular, 'dentated' serrations, the points of which are fixed at intervals to the dura mater. These
serrations are twenty-one in number on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

Surgical Anatomy.—Evidence of value in the diagnosis of meningitis may be obtained by the operation of lumbar puncture, that is, by puncturing the theca of the cord and withdrawing some of the cerebro-spinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebro-spinal fluid relieves the patient by diminishing the intracranial pressure. Lumbar puncture may give important diagnostic aid after a head injury by disclosing bloody cerebro-spinal fluid. The operation is performed by inserting a trocar, of the smallest size, below the level of the fourth lumbar vertebra. In an adult the cord terminates at the lower border of the first lumbar vertebra, and in a child opposite the body of the third lumbar vertebra. The canal may be punctured below the fourth vertebra without any risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra. In a child the puncture is made just below the vertebral spine. In adults one-half an inch to one side of the end of the vertebral spine. However the preliminary puncture is made, the needle penetrates the dura in the middle line. In entering the needle it should be directed upward and forward in a child; upward, forward, and slightly inward in an adult.

THE SPINAL CORD (MEDULLA SPINALIS) (Fig. 536).

The spinal cord is the cylindrical, elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half, its proportion to the encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance, which is continued for some distance into the filum terminale (Fig. 537). In the fetus, before the third month, it extends to the bottom of the sacral canal, but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that of the cord, so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. The spinal cord is cylindrical, being somewhat flattened
anteriorly and posteriorly (Fig. 538). On examining its surface it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The **cervical enlargement** (*intumescentia cervicalis*) extends from about the third cervical to the first or second dorsal vertebra; its greatest diameter is in the transverse direction (13 mm.), and it corresponds with the origin of the nerves which supply the upper extremities. The **lumbar enlargement** (*intumescentia lumbalis*) is situated opposite the last two or three dorsal vertebrae, and corresponds with the origin of the nerves which supply the lower extremities. Below the lumbar enlargement the cord gradually tapers to form a cone, the **conus terminalis** (*conus medullaris*), the apex of which is continuous with the filum terminale.

**Fissures and Grooves** (Fig. 538).—It presents on its anterior or ventral surface, along the middle line, a longitudinal fissure, the **anterior median or ventro-median fissure**, and on its posterior or dorsal surface another fissure, which also extends along the entire length of the cord, the **posterior median or dorso-median fissure or sulcus**. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide the cord into symmetrical halves, united in the middle line by a transverse band of nervous substance, the **commissure**.

The **Anterior Median or Ventro-median Fissure** (*fissura mediana anterior*) (Fig. 538).—The anterior median fissure is wider, but of less depth, than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the
lower part of the cord. It contains a prolongation from the pia mater, and its floor is formed by the anterior or white comissure, which is perforated by numerous blood-vessels passing to the centre of the cord.

The Posterior Median or Dorso-median Fissure or Sulcus (sulcus medianus posterior) (Fig. 538).—The posterior median sulcus is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one-half its width. The floor of the posterior median sulcus is formed by the posterior or gray comissure.

Lateral Fissures.—On each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the gray matter which approaches the surface in this situation; this is called the postero-lateral or dorso-lateral sulcus or fissure of the spinal cord (sulcus lateralis posterior). On the posterior surface of the spinal cord, between the posterior median fissure and the postero-lateral fissure on each side, is a slight longitudinal furrow, the posterior intermediate furrow or the posterior paramedian groove (sulcus intermedius posterior), marking off two slender tracts, the postero-median and postero-lateral columns. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord. On each side of the anterior median fissure the anterior roots of the spinal nerves emerge from the cord, not in one vertical line, but by separate bundles which occupy an area of some width. This is called, by some anatomists, the antero-lateral fissure of the cord (sulcus lateralis anterior), although no actual fissure exists in this situation.

Columns of the Cord (funiculi medullae spinalis) (Figs. 538 and 539).—Each half of the spinal cord is thus divided into four columns: an anterior column, a lateral column, a posterior column, and a postero-median column. This division, however, is very imperfect, since the limit between the so-called anterior and lateral columns cannot be defined on account of the bundles of the anterior roots being spread over
THE SPINAL CORD

839

a considerable area. It is therefore customary to divide each half of the spinal cord into two columns, separated by the postero-lateral sulcus: (1) a small posterior column (funiculus posterior), which is bounded internally by the posterior median fissure, and externally by the postero-lateral sulcus, and the posterior column is subdivided by the posterior intermediate septum into an outer portion, the column or tract of Burdach (fasciculus cuneatus), and an inner portion, the column or tract of Goll (fasciculus gracilis); (2) a large antero-lateral column, which comprises the rest of the cord. The antero-lateral column is divided arbitrarily into the lateral column (funiculus lateralis) and the anterior column (funiculus anterior).

Structure of the Cord (Fig. 538).—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nervous substance. The white matter is situated externally, and constitutes the greater part. The gray substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a transverse band of gray matter, the gray commissure. Each crescentic mass has an anterior or ventral horn (columna grisea anterior) and a posterior or dorsal horn (columna grisea posterior). The posterior horn is long and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the caput cornu; from this it tapers to form the apex cornu (apex columna grisea posterior), which at the surface of the cord becomes continuous with some of the fibres of the posterior roots of the spinal nerves. The constriction near the gray commissure is called the cervix cornu (cervix columna grisea posterior). The anterior horn is short and thick, and does not quite reach the surface, but extends toward the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. What is known as the lateral horn (columna grisea lateralis) projects from the outer aspect of the gray matter nearly on the line of the gray commissure. It is distinct in the upper dorsal region; in the cervical enlargement it is merged in the anterior horn, but it reappears in the upper cervical region. In the lumbar region it merges with the anterior horn. Owing to the projections toward the surface of the anterior and posterior horns of the gray matter, each half of the cord is divided by the gray matter, more or less completely, into three columns, anterior, middle, and posterior, the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

The Commissure of the Spinal Cord.—The commissure of the spinal cord is composed of white and gray matter, and is therefore divided into the white and gray commissure.

The Anterior or White Commissure (commissura anterior alba) is situated at the bottom of the anterior median fissure, and is formed of medullated nerve-fibres, which pass between the gray matter of the anterior horn and the anterior and lateral white columns of one side into similar parts on the other side. The fibres are oblique in direction; many which enter at the posterior part of the commissure on the one side leave it at the anterior part of the commissure on the other, and vice versa, a decussation taking place in the middle line.

The Posterior or Gray Commissure (commissura grisea), which connects the two crescentic masses of gray matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse medullated nerve-fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge; some pass backward to the posterior roots; others spread out, at various angles, into the crescent. The portion of the gray commissure in front of the central canal is called the anterior gray commissure (commissura grisea anterior); the portion behind the central canal is called the posterior gray commissure (commissura grisea posterior).

Running through the gray commissure of the whole length of the cord is a
minute canal, which is barely visible to the naked eye in the human cord, but is proportionately larger in some of the lower vertebrata. It is called the central canal (canalis centralis); it opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity, the inferior rhomboid fossa (fossa rhomboidae inferior). It is surrounded by an area of neuroglia, which, in the recent state, has a gelatinous appearance, and in which there are no nerve-fibres. This is sometimes called the substantia gelatinosa centralis. When hardened in alcohol or chromic salts it has a finely reticulated appearance. The canal is lined in the fuctus by columnar ciliated epithelium, but in the adult the cilia have disappeared, and the canal is filled with their remains.

The mode of arrangement of the gray matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the dorsal; short, but wider, in the lumbar region. In the cervical region the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region the gray matter is least developed, the white matter being also small in quantity. In the lumbar region the gray matter is more abundant than in any other region of the cord. Toward the lower end of the cord the white matter gradually ceases. The crescentic portions of the gray matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Blood Supply of the Cord.—Spinal branches are given off by the vertebral, ascending cervical, deep cervical, intercostal, lumbar, lumbar branches of the ilio-lumbar, lateral and middle sacral arteries. Many of these spinal arteries give branches to the cord and the branches reach the cord in the spinal nerve-roots and form three vascular chains in the cord. The arteries of the cord are the anterior spinal and the two posterior spinal, which take origin from the vertebral arteries (pp. 638 and 639). The anterior spinal lies at the surface of the anterior median fissure. The posterior spinal arteries descend on either side of the cord behind the posterior nerve-roots. The central supply of the cord is chiefly from the anterior spinal artery. It sends sulcal branches inward in the fissure toward the cord; and branches of these vessels enter the cord. The vessels of the cord are terminal arteries. The gray matter is chiefly supplied by the anterior spinal, partly by the posterior spinal. The white matter is supplied by both vessels. From the interior of the cord blood is brought by fissural veins (which emerge from the fissures), root-veins (which emerge with the fibres of the anterior and posterior roots), and a few veins which emerge from different parts of the surface of the cord. These vessels unite to form the medulli-spinal plexus, which is between the pia mater and the arachnoid membrane. (See Spinal Veins.)

Lymphatics.—There are no lymph-vessels in the cord, but lymph is collected by perivascular lymph-spaces and by spaces about the nerve-fibres.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the white substance; and of a central part, the gray matter, both supported in a stroma.

The stroma is composed of connective tissue, which is derived from the pia by ingrowth, and hence is of mesodermic origin, and of neuroglia.

The Neuroglia.—The neuroglia consists of a homogeneous transparent matrix, of a network of very delicate fibrille, and of small stellate or branched cells, the neuroglia-cells.

It takes origin from cells which were derived from the large columnar cells of the wall of the neural canal, and hence is of epithelial origin.

---

1 A Manual of Practical Anatomy. By the late Prof. Alfred W. Hughes. Edited and completed by Arthur Keith, M.D.
In addition to forming a ground substance, in which the nerve-fibres, nerve-cells, and blood-vessels are embedded, a considerable accumulation of neuroglia takes place in three situations: (1) on the surface of the cord, beneath the pia mater; (2) around the central canal, the *substantia gelatinosa centralis*; and (3) as a cap over the extremity of the posterior horn, forming the *substantia cinerea gelatinosa*.

The White Substance of the Cord (*substantia alba*).—The white substance of the cord is placed at the periphery and in the anterior commissure. It consists of medullated nerve-fibres, mostly disposed longitudinally, with blood-vessels and neuroglia, sustained by a network of connective tissue from the pia. When stained with carmine it presents a very striking appearance on transverse section. It is seen to be studded all over with minute dots, surrounded by white areas. This is due to the longitudinal medullated fibres seen on section. Each dot is an axis-cylinder, the white area about it is the substance of Schwann. Externally, the neuroglia forms a sheath closely investing the outer surface of the cord immediately beneath the pia mater; from it numerous septa pass inward and separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium, in which they are embedded. There are transverse, oblique or dorso-ventral and longitudinal fibres in the white substance.

Transverse Fibres. — These fibres pass between the longitudinal tracts of the cord and the gray matter. They constitute the anterior or white commissure, which joins the anterior and lateral white columns and the anterior gray horn of one side to like parts of the opposite side.

As previously stated, it is in front of the gray commissure, and is the floor of the anterior median fissure. It contains four sets of fibres: (1) those belonging to the direct pyramidal tract, (2) those belonging to the antero-lateral ground bundle, (3) those belonging to the antero-lateral ascending cerebellar tract, (4) crossed fibres to the anterior spinal nerve-roots.¹

Oblique or Dorso-ventral Fibres. — These are the anterior root-fibres passing from the anterior gray horn to the periphery of the cord and the posterior root-fibres passing from the periphery of the cord to the posterior gray horn.

Longitudinal Fibres. — They constitute the conducting tracts (Fig. 539).

It is impossible to trace the course of the nerve-fibres in their passage through the cord; but the investigation of pathological lesions has shown that the white matter of the cord consists of certain columns or tracts of fibres; for it has been found that certain lesions are strictly limited to certain well-determined parts of the cord without involving neighboring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special

functions, seems abundantly proved by the researches of Flechsig and others on the development of the spinal cord during the later periods of utero-gestation and in the newly born infant. By these researches several tracts can be traced along the greater part of the cord and into or from the encephalon (Fig. 539). Thus (1) in the antero-lateral column of the cord, on either side of the anterior median fissure, a portion of the column may be divided off as the uncrossed or direct pyramidal tract or the fasciculus of Turck (fasciculus cerebrospinalis anterior [ventralis]). This tract is a continuation of the corresponding tract in the medulla. It is only found in the upper part of the cord; it gradually diminishes as it is traced downward, and disappears about the middle of the dorsal region. It consists of centrifugal or descending fibres which can be traced downward from the pyramid of the medulla of the same side, and are derived from the motor area of the cerebral cortex. The fibres of this tract decussate in their course down the cord, passing across the middle line through the anterior white commissure and terminating in the anterior gray horn of the opposite side; this explains the gradual diminution and eventual disappearance of the tract. (2) In the hinder part of the antero-lateral column is a somewhat triangular area, larger than the preceding, which is named the crossed pyramidal tract (fasciculus cerebrospinalis lateralis). In the cervical and dorsal regions the crossed pyramidal tract is overlaid by the direct cerebellar tract, but in the lumbar cord it is at the surface. This also consists of descending fibres, which are derived from the pyramid of the medulla of the opposite side, and which have crossed in the decussation of the pyramids. After crossing in the medulla the fibres descend and terminate about the cells in the anterior cornu of the same side as the column. The fibres are derived from the motor area of the cerebral cortex of the opposite side. Thus it will be seen that all the fibres from the motor area, which descend through the internal capsule, the crus cerebri, and the pons Varolii to the pyramidal body of the medulla, decussate. Some decussate in the lower part of the medulla, and descend through it as the crossed pyramidal tract. Others do not decussate in the medulla but descend as the direct pyramidal tract and cross through the anterior commissure of the cord to terminate in the anterior gray horn of the opposite side, where the fibres end by forming synapses around its cells. Investigations render it probable that the crossed pyramidal tract contains some fibres from the main pyramidal tract in the medulla, which have descended from the corresponding side of the brain undecussated and terminate about the cells of the gray cornu of the same side of the cord. The crossed descending tract of the red nucleus is found within the crossed pyramidal tract at the junction of its lateral and dorsal portions. This tract from the opposite red nucleus reaches the lumbar cord and ends in the gray matter. (3) The antero-lateral tract is an extensive crescent-shaped strand which skirts the circumference of the anterior three-quarters of the antero-lateral column of the cord. Behind, where it is thickest, it lies in the angle formed by the direct cerebellar and crossed pyramidal tracts, becoming narrower as it passes forward toward the direct pyramidal tract. It contains two sets of fibres, centripetal or ascending, and centrifugal or descending, and hence is divided into two tracts, the antero-lateral ascending and the antero-lateral descending cerebellar tracts. (a) The antero-lateral ascending cerebellar tract or the column of Gowers (fasciculus anterolateralis superficialis ascendens) is chiefly in the posterior part of the antero-lateral tract, although some of its fibres mingle with the descending tract. The axones which compose this tract arise from cells in the central gray matter and the gray matter of the base of the anterior horn, chiefly from the opposite side of the cord (Santee), most of the fibres crossing soon after their beginning by way of the anterior commissure. The fibres of the column of Gowers pass through the dorsal portion of the lateral region of the medulla (sending nerve fibres to the lateral nucleus) and the formation reticularis of the pons, turn backward over the superior peduncle of the cerebellum, and
pass into the superior vermis through the valve of Vieussens (Santee, from Hoche). Between the ascending and descending tracts is the olivary bundle of the cord or the triangular tract of Helwig (tractus triangularis [Helwig]). It arises in the lumbar cord and terminates in the olive of the medulla. (b) The antero-lateral descending cerebellar tract or the column of Marchi and Lowenthal (fasciculus anterolateralis superficialis descendens) is situated chiefly in the anterior portion of the antero-lateral tract, but some of its fibres are scattered among the fibres of Gowers' column. The axones of the descending tract are derived from Purkinjean cells in the cerebellar cortex. The fibres pass through the inferior peduncle of the cerebellum and the lateral region of the medulla and terminate in the anterior gray horn. (4) The direct cerebellar or dorso-lateral cerebellar tract (fasciculus cerebellospinalis) is situated at the circumference of the cord behind the preceding and external to the crossed pyramidal tract, occupying a narrow area which extends backward as far as the posterolateral fissure or nearly so. It commences at the upper level of the lumbar cord. Below this level it is absent, and where it is absent the crossed pyramidal tract reaches the surface. As the direct cerebellar tract ascends it increases in size. It passes through the restiform body of the medulla and terminates in the superior vermis of the cerebellum. Its fibres are derived from the cells of the posterior vesicular column of Clerke in the gray matter of the cord. (5) Close to the point where the posterior roots enter the cord, in the antero-lateral column, is a small collection of fibres, which is known as the marginal tract of Spitzka and Lissauer (fasciculus marginalis); it is formed by some of the outer fibres of the posterior roots which run upward in the tract for a short distance, and end about the cell-bodies of the substantia gelatinosa (Santee). (6) The rest of the antero-lateral column of the spinal cord is occupied by the antero-lateral ground bundle (fasciculus proprius anterolateralis). It surrounds the anterior cornu and separates the antero-lateral tract and the crossed pyramidal tract from the gray matter of the cord. Nowhere does it reach the surface of the cord, but at one place it very closely approaches it. The direct pyramidal tract separates it from the anteromedian fissure. The fibres are very short and are commissural and associative. The portion of the ground bundle in the anterior column is chiefly commissural, its fibres passing between the anterior cornua. The portion in the lateral column is chiefly for association, its fibres joining different areas of the cord on the same side. It consists of (a) longitudinal fibres. A posterior longitudinal bundle (fasciculus longitudinalis medialis), which ascends to reach the motor nuclei of cranial nerves and the subthalamic region. An anterior longitudinal bundle (fasciculus ventralis) passes from the superior corpus quadrigeminum to the cilio-spinal and other centres (Santee). Longitudinal commissural fibres, which unite the groups of cells in the gray matter with one another; (b) of fibres which pass across the anterior commissure from the gray matter of the opposite side; and (c) horizontal fibres belonging to the anterior roots of the nerves, which pass through it before leaving the cord. In the posterior column of the cord there are two definite tracts. They are marked off from each other by the posterior intermediate furrow on the surface of the cord. The part which has been described previously as the posterior median column pretty nearly corresponds to the one tract, the tract of Goll, and the remainder of the posterior column corresponds to the other, the tract of Burdach. (7) The postero-median tract or tract of Goll (fasciculus gracilis) increases as it ascends, and consists of long, but small, fibres derived from the posterior roots of the spinal nerves, which ascend to the medulla oblongata, the fasciculus gracilis of the medulla, and end in the nucleus gracilis. Some fibres leave the tract and end in the gray matter of the cord. A few fibres pass to the thalamus and a few to the cerebellum. (8) The postero-lateral tract or the tract of Burdach (fasciculus cuneatus) consists of shorter, but larger, fibres than the preceding; they are derived from the posterior roots and from cells in the gray
matter of the cord; some ascend only for a short distance in the tract and then enter the gray matter and come into close relationship with the cells of the posterior vesicular column of Clarke; others incline toward the mesial plane, and, entering Goll's column, can be traced as far as the medulla. The tract of Burdach becomes in the medulla the fasciculus cuneatus and the fasciculus of Rolando. Some of its fibres continue along the interolivary fillet, others along the arciform fibres, and some terminate in the gray matter of the cord (Santee). In the cervical and upper dorsal regions there is contained in the substance of Burdach's column a small strand of fibres, called the descending comma tract. It presents, on transverse section, the appearance of a comma, the blunt extremity of which is directed forward. The fibres forming it probably represent in part descending portions of the dorsal nerve-roots, together with descending commissural fibres within the cord itself.

What is known as the cornu commissural tract is in the lumbar and lower dorsal regions, between the posterior cornu and the gray commissure. The septo-marginal tract is only found in a portion of the lumbar cord. It is between the septum and the dorsal surface of the cord (Santee).

Functions of the Various Tracts in the Cord.—1. The direct pyramidal tract is motor, and conveys impulses chiefly to the arms and trunk. It conducts motor impulses from the cerebral cortex of one side, along the spinal cord of the same side, and to the multipolar nerve-cells of the anterior horn of the opposite side of the cord. A given muscular region is supplied chiefly by the crossed pyramidal tract of the corresponding side of the cord and partly by the direct pyramidal tract of the opposite side of the cord, but both tracts are innervated by the same brain area. It is further to be remembered that there are probably direct or uncrossed fibres in the crossed pyramidal tracts of the cord which convey motor impulse from the cortex to muscles of the same side.

2. The crossed pyramidal tract conveys motor impulses and impulses which control reflex movements. It descends from the cortex, decussates in the lower part of the medulla, and descends in the cord on the side opposite to the brain area from which it arose. It supplies muscles on the same side of the body as the tract is of the cord. This tract also contains a few uncrossed fibres from the same side of the brain. Hence the muscles of one side receive their chief innervation from the opposite side of the brain by way of the crossed and the direct pyramidal tracts, but receive some slight innervation from the same side of the brain by way of the direct fibres in the crossed pyramidal tract. Gowers¹ says: "There is abundant evidence that each hemisphere of the brain is connected with both legs, although chiefly with that of the opposite side. There is also a similar and even more equal connection with the trunk muscles, and a slighter connection with certain muscles of the arm. Such muscles invariably regain some power on the paralyzed side, even with a complete interruption to the motor path, and they are weakened on the unparalyzed side."

3. The antero-lateral descending cerebellar tract is a "segment of an indirect motor path" (Santee). The antero-lateral ascending cerebellar tract conveys impressions of temperature and pain.

4. The direct cerebellar tract conveys impressions of equilibrium, particularly from the viscera.

5. The antero-lateral ground bundle is associative between the anterior cornua and is commissural between different segments of the cord. These commissural and associative connections are of great importance, for if the regular route of nervous conduction is interrupted they may serve to convey the nerve current around the block.

¹ Diseases of the Nervous System.
6. The marginal tract of Spitzka and Lissauer is composed of ascending fibres from the posterior nerve-roots.

7. The postero-lateral tract conveys impressions of common sensation.

8. The postero-median tract conveys impressions of muscular sense.

The Gray Substance of the Cord (substantia grisea).—The gray substance of the cord occupies its central part in the shape of two crescentic horns, joined together by the gray commissure. Each of these crescents has an anterior or ventral and a posterior or dorsal horn.

The Posterior or Dorsal Horn (columna grisea posterior) consists of a slightly narrowed portion, at its base, where it is connected with the rest of the gray substance—this is, the cervix cornu; from this it gradually expands into the main part of the horn, the caput cornu, and tapers to form the apex cornu; around its extremity is a lamina or layer of gelatinous material, which covers the head like a cap, and from this it tapers almost to a point, which approaches the surface of the cord at the postero-lateral groove.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein) similar to that found around the central canal, and has been named by Rolando the substantia cinerea gelatinosa. It probably takes its origin from the columnar cells which line the posterior part of the embryonic spinal canal.

The Anterior or Ventral Horn of the Gray Substance (columna grisea anterior) in the cervical and lumbar swellings, where it gives origin to the motor nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, a lateral horn (columna grisea lateralis) is found projecting outward from the lateral region of the gray matter on a level with the gray commissure in the upper part of the dorsal region of the cord; in the cervical and lumbar regions this lateral horn blends with the anterior horn, which thus becomes broad and expanded. From the concavity of the crescent, between the anterior and posterior horns, processes of gray matter extend into the white substance, where they divide and anastomose to form a network, termed the formatio reticularis.

The gray commissure contains the central canal (canalis centralis), and is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The gray substance of the cord is composed of—(1) the substantia gelatinosa, which envelops the head of the posterior horn and which encircles the central canal of the cord; (2) the substantia spongiosa, which forms the crescentic horns (except the heads of the posterior horns and the envelope of the central canal). Further, it may be stated that the gray matter consists of nerve-fibres of variable but smaller average diameter than those of the white column; (3) nerve-cells of various shapes and sizes, with from two to eight processes; (4) blood-vessels and connective tissue.

The nerve-fibres of the gray matter of the posterior horn are for the most part composed of a dense interlacement of minute fibrils, intermingled with nerves of a larger size. This interlacement is formed partly by the axones and dendrites of the cells of the gray matter, and partly by fibres which enter the gray matter and which come from various sources.

The nerve-cells of the gray matter are collected into groups as seen on transverse section, but they really form columns of cells placed longitudinally; or else they are found scattered throughout the whole of the gray matter.

In the anterior horn the cells consist of two chief groups; one medial, the more constant, near the anterior column; the other lateral, near the lateral column. The axones of these cells constitute the bulk of the anterior roots of the spinal nerves. The spinal nerves obtain axones from the entire lateral gray column and
from part of the medial gray column of the same side, and also from the gray matter of the medial column of the opposite side by way of the white commissure. The nerve-fibres from these cells are distributed to the muscles of the trunk and extremities. A second lateral group is present in the cervical and lumbar enlargements. In the centre of the gray crescent (substantia intermedia grisea) the cells are collected into three groups or columns. The intermedio-lateral column runs throughout the length of the cord, but is most distinct in the thoracic region. Its cells are in relation with fibres from the posterior nerve-roots and send off axones to the anterior nerve-roots. It is believed by Morris and others that these fibres are sympathetic and pass to glands and blood-vessels. Other axones enter the antero-lateral ascending cerebellar tract (Santee). The middle column is most distinct in the cervical cord. It certainly receives fibres from the posterior roots, and possibly sends fibres to the antero-lateral ascending cerebellar tract. At the base of the posterior horn on its inner side, adjoining the gray commissure, is a group of nerve-cells, called Clarke's posterior or dorsal column or Clarke's vesicular column (nucleus dorsalis), which extends from the eighth cervical to the second lumbar nerve. In the cervical and lumbar cord the nuclei of Stilling are its representatives, and in the medulla the accessory cuneate nucleus represents it. This column

is in relation with the fibres of the posterior nerve-roots, and the axones from the cells of the column compose the direct cerebellar tract, and some, which are sympathetic, enter the anterior roots of the spinal nerves. In the posterior cornu are many cells not definitely arranged, but groups which are named peripheral, central, and basal. The axones of the cells of the posterior cornu enter the ground bundles, the column of Burdach, the anterior cornu of the same side, and the anterior and posterior cornua of the opposite side. Many fibres of the posterior roots are in relation with the cells of the posterior cornu.

At the junction of the anterior and posterior cornua, in the outer portion of the gray matter, is a third group of cells, the lateral cell column; this is best seen in the dorsal region. In certain regions of the cord these cells extend in among the fibres of the white matter of the lateral column, and give rise to the lateral horn.
In addition to these groups a few large scattered cells are found in the posterior horn and in the substantia gelatinosa of Rolando.

**Origin of the Spinal Nerves** (Figs. 538 and 540).—The roots of the spinal nerves are attached to the surface of the cord, opposite the horns of gray matter.

A **Posterior Nerve-root** enters the cord in two bundles, **medial** and **lateral**. The medial strand consists of coarse fibres which enter the outer part of the column of Burdach. The lateral strand is sometimes divided into a middle and an external bundle. The former contains large fibres, and passes through the gelatinous substance of Rolando into the posterior horn. The external bundle consists of fine fibres which assume a longitudinal direction in the Spitzka-Lissauer tract. All the posterior root-fibres divide into ascending and descending branches on entering the cord, and these in their turn give off collaterals (Fig. 541). The fibres and their collaterals terminate by forming arborescences, some around the cells in the posterior horn, and others around the cells of Clarke's column, while the long ascending branches pass up in the columns of Goll and Burdach, and end by arborizing around the cells in the gracile and cuneate nuclei. Some of the fibres, however, pass to the gray matter of the opposite horn, and others to the anterior horn of the same side of the cord.

**Anterior Nerve-roots**.—The majority of the fibres of the anterior nerve-roots are the continuations outward of the axones of the large or small multipolar cells in the anterior horn of gray matter. Some, however, appear to pass across in the anterior a white commissure to the cells in the anterior horn of the opposite side, while others extend backward to the posterior horn and outward to the lateral column of the same side.

**THE MENINGES OR MENINGEAL MEMBRANES OF THE BRAIN** (MENINGES ENCEPHALI).

**Dissection**.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about an inch above the margin of the orbit, and extending, behind, to a little above the level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.

The membranes of the brain are from without inward: the **dura mater**, **arachnoid membrane**, and the **pia mater**.

**The Dura Mater of the Brain (Dura Mater Encephali)** (Figs. 543, 544, 545, 547).

The **dura mater** of the brain is a thick and dense inelastic fibrous membrane which lines the interior of the skull. It is a covering for the brain and is also the internal periosteum. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones by fibrous processes and blood-vessels. The adhesion is most marked on bony projections, opposite the sutures and at the base of the skull. Except at the sutures the adhesions are not dense, and between the fibrous processes which pass to the bone are spaces which are thought to be lymph-spaces, and are called **epidural spaces**. At these points the outer surface of the dura is covered with endothelium. Fibrous tissue passes through the open sutures and joins the outer layer of the dura to the external periosteum. It is known as the **sutural membrane**. The inner surface of the dura limits the **subdural space**. It is smooth and lined by a layer of endothelium. The dura mater sends four processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which
exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen caecum; it sends a series of tubular prolongations around the filaments of the olfactory nerves as they pass through the cribiform plate, and also around the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process into the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. The cavity or cave of Meckel (cavum Meckeli) (Fig. 545) is an osteo-fibrous recess near the apex of the petrous portion of the temporal bone, formed by folding of the dura mater in a bony depression. It contains the GAS-serian ganglion. In certain situations, as already mentioned (p. 736), the fibrous layers of this membrane separate to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small, whitish bodies, the glandulae Pacchioni (p. 854).

Structure (Fig. 542).—The dura mater consists of white fibrous tissue with connective-tissue cells and elastic fibres arranged in flattened laminae, which are imperfectly separated by lacunae, spaces and blood-vessels into two layers, endosteal and meningeal. The endosteal layer is the internal periosteum for the cranial bones and contains the blood-vessels for their supply. At the margin of the foramen magnum it becomes continuous with the periosteum lining the spinal canal. The meningeal or supporting layer is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes; these cells were formerly regarded as belonging to the arachnoid membrane. By its reduplication the meningeal layer forms the falx cerebri, the tentorium and falx cerebelli, and the diaphragma sellae. The two layers are connected by fibres which intersect each other obliquely.

The Arteries of the Dura Mater (see section on Arteries).—Its arteries are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. In the middle fossa are the middle and small meningeal branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis craniai, branches from the internal carotid, and a recurrent branch from the lachrymal. In the posterior fossa are meningeal branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal,
from the vertebral; occasionally meningeal branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen, and a branch from the middle meningeal.

The Veins of the Dura Mater.—The veins which return the blood from the dura mater (see p. 734), and partly from the bones, anastomose with the diploic veins (see p. 733). These vessels terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein; above, the meningeal veins communicate with the superior longitudinal sinus. The sinuses are considered on pages 736 to 743 inclusive. On either side of the superior longitudinal sinus, especially near its middle, and also near the lateral and straight sinuses, are numerous spaces in the dura mater which communicate with the sinus, either by a small opening or a distinct venous channel. These spaces are the parasinoidal sinuses (lacunae laterales) (Fig. 453). Many of the meningeal veins do not open directly into the sinuses, but indirectly through the parasinoidal sinuses. These venous lacunae are often invaginated by Pacchionian bodies, and they communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The Lymphatics of the Dura Mater.—The existence of lymphatic vessels is not proved. Some anatomists claim to have injected such vessels along the middle meningeal arteries (Mascagni, Arnold). Perivascular lymph-spaces do exist.

The Nerves of the Dura Mater.—The nerves of the dura mater are filaments from the fourth, the ophthalmic division of the fifth, the Gasserian ganglion, the pneumogastric, the hypoglossal, and the sympathetic.

Processes of the Dura Mater (processus durae matris).—The processes of the dura mater, sent inward into the cavity of the skull, are four in number: the falc cerebri, the tentorium cerebelli, the falc cerebelli, and the diaphragma sellae.

The Falc Cerebri (Figs. 543 and 545).—The falc cerebri, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull, in the
middle line, as far back as the internal occipital protuberance; it contains the superior or great longitudinal sinus (sinus sagittalis superior). Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus (sinus sagittalis inferior). The straight sinus (sinus rectus) is formed by the attachment of the falx cerebri to the tentorium cerebelli.

The Tentorium Cerebelli (Figs. 543, 544, and 545).—The tentorium cerebelli is an arched lamina of dura mater, elevated in the middle and inclining downward toward the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses on each side the lateral sinus (sinus transversus); in front, to the superior margin of the petrous portion of the temporal bone on either side, enclosing the superior petrosal sinus (sinus petrosus superior); and at the apex of this bone the free or internal border and the attached or external border meet, and, crossing one another, are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the falx cerebri is attached, the straight sinus being placed at their point of junction. Its anterior border is free and concave, and with the dorsum sellae forms a large oval opening. This opening is called the incisura tentorii and transmits the mesencephalon.

The Falx Cerebelli (Fig. 543).—The falx cerebelli is a small triangular process of dura mater received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of
the tentorium; its posterior margin, to the lower division of the vertical crest on
the inner surface of the occipital bone. As it descends it sometimes divides into
two smaller folds, which are lost on the sides of the foramen magnum.

**The Diaphragma Sellae** (Fig. 544).—The diaphragma sellae is a horizontal process
formed by a reduplication of the meningeal layer of the dura mater. It forms
a small circular fold, which constitutes a roof for the sella turcica. This almost

The term arachnoid is from the Greek ἄραχνις, like a spider’s web, so
named for its extreme thinness. The cranial arachnoid is a delicate membrane
which envelops the brain, lying between the pia mater internally and the dura
mater externally; from this latter membrane it is separated by a very fine slit or
space, the subdural space (cavum subdurale). The subdural space contains a very
minute quantity of fluid of the nature of lymph. This fluid obtains exit by way
of the parasinoidal sinuses. The subdural space is prolonged upon emerging
nerves and joins the lymph spaces of the nerves. The subdural space does not
communicate with the subarachnoid space.

The arachnoid invests the brain loosely, being separated from direct contact
with the cerebral substance by the pia mater, and a quantity of loose areolar
tissue, the subarachnoideal areolar tissue. On the upper surface of the cere-
brum the arachnoid is thin and transparent, and may be easily demonstrated by

---

**The Arachnoid Membrane (Arachnoidea Encephali)** (Fig. 546).

---

![Image of brain with arachnoid membrane labeled](image-url)
injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them, but does pass into the Sylvian and great longitudinal fissures and is prolonged upon the nerves as a sheath. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the orbital surface of the anterior lobes, and extends across between the two temporal lobes so as to leave a considerable interval between it and the brain, the cisterna basalis.

The Subarachnoid Space (cavum subarachnoideale) (Fig. 547).—The subarachnoid space is the interval between the arachnoid and pia mater. It is not only on

the surface, but dips between the convolutions. It is not, properly speaking, a space, for it is occupied everywhere by a spongy tissue consisting of trabeculae of delicate connective tissue covered with endothelium, which pass from the pia mater to the arachnoid, and in the meshes of which the subarachnoid fluid is contained. This so-called space is small on the surface of the hemispheres; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger.

In certain regions the arachnoid and pia are farther apart than was previously indicated, and these spaces are called subarachnoid cisternae (cisternae subarachnoideal). The largest space is the continuation of the posterior part of the subarachnoid space of the spinal cord. It is called the posterior subarachnoid space.
or cisterna magna (cisterna cerebellomedullaris). It is a space formed by the arachnoid passing across the back and under portions of the medulla and cerebellum. It communicates with the fourth ventricle by three foramina. The largest opening is the foramen of Majendie (apertura medialis ventriculi quarti). It is in the middle line of the tela choroidea inferior. At the end of each recessus lateralis of the fourth ventricle there is also an opening, and each opening is called the foramen of Key and Retzius (apertura latus ventriculi quarti). The cisterna pontis is the continuation upward of the anterior part of the subarachnoid space of the cord. About the medulla it is continuous with the cisterna magna, so this important nerve centre is surrounded by a large subarachnoid space. The cisterna basalis (cisterna interpeduncularis) is formed by the arachnoid extending between the two temporal lobes, and it contains the arteries forming the circle of Willis. The anterior subarachnoid space (cisterna pontis, interpeduncularis et chiasmatis) includes the cisterna pontis, the cisterna basalis and the cisterna of the chiasm. There is a cisterna between the inferior edge of the falx cerebri and the superior surface of the corpus callosum which contains the anterior cerebral arteries, a cisterna in the fissure of Sylvius which contains the anterior cerebral artery, and a cisterna between the corpora quadrigemina which contains the vena magna Galeni.

It is stated by Merkel that the lateral ventricles also communicate with the subarachnoid space at the apices of their descending horns.

The cerebro-spinal fluid (liquor cerebrospinalis) fills the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

Structure.—The arachnoid consists of bundles of connective tissue, the fine fibres of which form one layer and cross each other in every direction. At the level of the large fissures, and especially around the circle of Willis, it is reinforced by thick fibrous tissue. Both surfaces are covered with endothelium. There are no blood-vessels in the arachnoid; the vessels which appear to be in it are really in the pia. There is no positive proof that nerves are present in the arachnoid. It is true that Bochdalek and Luschka long ago described arachnoid nerves, but these observations have never been corroborated.
Glandulae Pacchioni, Luschka's Villi or the Arachnoid Villi (Granulationes Arachnoideales).

The glandulae Pacchioni are numerous small whitish or purplish projections, usually collected into clusters of variable size, which are found in the following situations: 1. Upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the dura mater. 3. In the superior longitudinal sinus and the other sinuses. 4. On the pia mater, near the margin of the hemispheres.

A hasty examination would lead us to suppose that these bodies spring from the dura, but, as a matter of fact, they originate from the arachnoid. They are not glandular in structure, but are simply enlarged normal villi of the arachnoid. In their growth they appear to perforate the dura mater, and when a group of villi is of large size it causes absorption of the bone, and comes to be lodged in a pit or depression (foveola granularis [Pacchioni]) on the inner table of the skull. Their manner of growth is as follows: at an early period they project through minute holes in the inner layer of the dura mater, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura mater before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the dura mater and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed is continuous with the trabecular tissue of the sub-arachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies, and through their coverings filters into the superior longitudinal sinus. They are supposed to be a means of getting rid of an excess of cerebro-spinal fluid, when its quantity is increased above normal. Another means of getting rid of cerebro-spinal fluid is absorption by the lymph-spaces of the cranial nerves, which possess sheaths of arachnoid up to the points at which they emerge from the skull.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the tenth year; and from this period they increase in number as age advances. Occasionally they are wanting.

The Pia Mater of the Brain (Pia Mater Encephali) (Figs. 547, 548).

The pia mater of the brain is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminae, and is prolonged into the interior, forming the velum interpositum and the choroid plexuses of the lateral and fourth ventricles.

The Velum Interpositum or the Tela Chorioidea Superior (tela chorioidea ventriculi tertii) (Fig. 548).—The velum interpositum is the prolongation of the pia mater into the interior of the brain through the middle of the transverse fissure. It is a double triangular vascular fold, lies between the body of the fornix above and the optic thalamus and the epithelial roof of the third ventricle below, and passes forward to the foramen of Monro. At each edge of the velum interpositor is the choroid plexus (plexus chorioideus ventriculi lateralis) of the corresponding lateral ventricle. In front the two plexuses join behind
Fig. 548.—Velum interpositum. (Poirier and Charpy.)

Fig. 549.—The anterior cerebral and choroid arteries. (Spalteholz.)
the foramen of Monro, and at the point of junction two lesser choroid plexuses pass back along the under surface of the velum to the third ventricle, the median plexus \( \text{(plexus chorioideus ventriculi tertii)} \). The veins of Galen or the deep cerebral veins (p. 735) are two veins which lie on either side of the middle of the velum interpositum and pass back. Each vein of Galen is formed by the union of the vein from the corpus striatum and the choroid vein from the choroid plexus. The two veins of Galen unite and form the \text{vena magna Galeni}, which empties into the straight sinus.

The pia mater of the surfaces of the hemispheres, where it covers the gray matter of the convolutions, is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the gray substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia mater of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upward over the medulla it is seen to preserve these characters. At the upper border of the medulla it is prolonged over the lower half of the fourth ventricle, forming a covering for it called the \text{tela chorioidea inferior (tela chorioidea ventriculi quarti)}, before it is reflected on to the under surface of the cerebellum, and which carries the \text{choroid plexus of the fourth ventricle (plexus chorioideus ventriculi quarti)}. The arteries of the pia mater (see pp. 626, 627, and 628) (Figs. 549 and 550) are the anterior cerebrials, middle cerebrials, posterior cerebrials, anterior cho-roidids, the superior cerebellars, and the anterior and posterior inferior cerebellars. (The vessels of the cerebral ganglionic system and of the cortical arterial system are considered on pp. 630 and 631.)

The veins of the pia mater (see pp. 734, 735, and 736) are the basilar vein, the veins of Galen (Fig. 548), the veins constituting the choroid plexuses of the

---

**Fig. 550.**—The arteries of the medial surface of the right cerebral hemisphere. (Spalteholz.)
third ventricle, the lateral ventricles, and the fourth ventricle; the cerebral veins (Fig. 546) and the cerebellar veins (Fig. 546).

The nerves of the pia mater accompany the branches of the arteries and are derived from the sympathetic and from the third, fifth, sixth, seventh, ninth, tenth, and eleventh cranial nerves.

According to Fohmann, Arnold, and Mascagni, this membrane contains numerous lymphatic vessels, but the question is uncertain.

THE BRAIN (ENCEPHALON).

The encephalon or brain is that portion of the cerebro-spinal axis which is contained in the cavity of the cranium.

The Development of the Brain.—The nervous system (brain, ganglia, spinal cord, and nerves) is derived from the ectoderm (the epiblastic layer of the blastodermic vesicle). This, it will be remembered, is an epithelial layer, and nervous structure is composed of epithelial cells variously modified. The embryonal area of the surface of the developing germ is a white spot, which at first is round, but becomes pear-shaped and develops a transverse ridge, the terminal ridge, on its posterior margin. From the embryonal layer, and from this alone, the new individual is developed.

About the twelfth or the thirteenth day of the development of the human embryo, cell-proliferation occurs at a certain portion of the under surface of the ectoderm. This proliferation gives rise to a white, longitudinal streak in the embryonal area, known as the primitive streak or axis plate. The head process of the primitive streak appears somewhat later, and is situated directly in front of the anterior end of the streak.

At the anterior end of the primitive streak is a group of epiblastic cells known as Hensen's node. The epiblastic cells of the head-process of the primitive streak enlarge and become columnar, and the cells at each side of the streak become flat (Heisler). Thus is formed from the ectoderm the medullary plates; and the turning up of the edge of the medullary plates forms the spinal or medullary furrow or groove. As the curling up of the edges of the medullary plates continues the groove deepens, finally becoming a tube known as the medullary or neural tube or canal.

The neural tube lies beneath the ectoderm; is finally separated from it; runs from one end of the body to the other; forms the primitive nervous system, and gives origin to the entire nervous system. The constricted portion between the hind-brain and the mid-brain is known as the isthmus rhombencephali.

It is thus seen that the medullary or neural groove is converted into a canal, the neural canal. Its cephalic end dilates into a sac, from which the brain is developed, and the remainder forms the spinal cord. In consequence of the curve that the cephalic portion of the embryo undergoes, a marked bend in the canal takes place forward, so that the plane of the ventricles is placed almost at a right angle with the long axis of the central canal of the cord. The rudimentary brain consists of a hollow sac—the rudimentary cord of a hollow canal. The sac and the canal communicate freely with each other.

The sac elongates, and in it appear two constrictions, which partially divide it into three portions, namely, the anterior, middle, and posterior primitive cerebral vesicles, or the fore-brain (prosencephalon), the mid-brain (mesencephalon), and the hind-brain (rhombencephalon) (Fig. 551). Subsequently the anterior and the posterior vesicles become constricted, each into two, while the middle remains undivided (Figs. 553 and 554). It will thus be seen that at the anterior extremity of the medullary canal there are five dilatations, separated from each
other by constrictions, through which, however, they freely communicate with one another. These five vesicles are the fundamental or primitive divisions of the adult brain. They are named, from before backward, the fore-brain (prosencephalon), the inter-brain (thalamencephalon, formed from the prosencephalon), the mid-brain (mesencephalon), the upper portion of the hind-brain (metencephalon), and the lower portion of the hind-brain (myelencephalon). The constricted portion between the hind-brain and the mid-brain is known as the isthmus rhombencephali.

These five vesicles are at first fairly uniform in size and in shape, but they soon begin to grow at different rates and to assume different forms. The changes are most marked in the first vesicle.
The first secondary vesicle sends out two hollow protrusions, one on each side, from the forepart of its lateral surface. These grow rapidly, spread out, and extend forward, laterally, and backward, over the sides of the first and second ventricles, forming large cavities, which become the lateral ventricles (Fig. 552, G). From each protrusion three prolongations take place: one forward and outward; the second backward and inward, and the third at first backward, outward, and downward, and then forward and inward. These prolongations form the horns of the lateral ventricles, and they far exceed in size the original vesicle from which they have taken origin, which does not increase to any great extent, but remains as the anterior part of the third ventricle. The communication between it and the future lateral ventricle persists as the foramen of Monro (Fig. 552).

The second vesicle or thalamencephalon becomes elongated from before backward and compressed laterally, so as to form the greater part of the third ventricle (Fig. 552, B). From each side of that part of the fore-brain, which ultimately becomes the lateral ventricle, is budded off a hollow projection, the primary optic vesicle, that is developed eventually into the optic nerve and the retina. It will be considered later.

The constriction between the first and the second vesicle disappears, so as to throw the whole cavity of the future third ventricle, formed by the remains of the first ventricle and the whole of the second vesicle, into one.

The third vesicle or mesencephalon forms a very insignificant part of the brain of the adult. It constitutes a stem of junction between the parts that take origin from the rhombencephalon and those that arise from the prosencephalon. The wall of the mesencephalon is completely converted into nerve-tissue, and forms the corpora quadrigemina, the two crura cerebri, and the aqueduct of Sylvius, which join the third ventricle with the fourth.

The metencephalon gives origin to the cerebellum and the pons Varolii. The cerebellum takes origin from a thickening of the superior wall of the vesicle, while the pons takes origin from a thickening of the lateral and inferior walls of the vesicle.

The myelencephalon gives origin to the bulb or medulla oblongata, chiefly by a thickening of the lateral walls of the vesicle. The original hind-brain remains in the brain of the adult as the fourth ventricle.

As already stated, these vesicles do not remain in the same plane. The formation of certain definite flexures alters the position of the vesicles with regard to one another (Fig. 554). The cephalic flexure is opposite the base of the mid-brain, which becomes sharply bent upon itself over the end of the notochord. This bending causes the mid-brain to become the most prominent part of the encephalon on the convexity of the curve. The pontine or pontal flexure is a curve in the hind-brain, in the opposite direction to that of the cephalic flexure. At the junction of the
hind-brain with the spinal cord is the **cervical** or nuchal flexure. In the development of the brain the cephalic flexure remains permanent, but the other two flexures completely disappear.

The manner in which the different parts of the encephalon are formed from the walls of this greatly altered medullary canal will now be considered, it being remembered that the ventricles are developed, as previously described, from the five secondary vesicles.

The first vesicle, or prosencephalon, sends out two hollow protrusions, which spread rapidly, and in the walls of these nervous matter is developed, which constitutes the cerebral hemispheres (Fig. 554, II), the cavities remaining as the lateral ventricles. As these hemispheres extend they grow forward in front of the anterior extremity of the primitive brain, and lie side by side, separated by the longitudinal fissure; they also grow upward, and again lying side by side are separated by another portion of the same fissure, containing a thin layer of mesoblast, which forms the falx cerebri; behind and laterally they overlap the roof and sides of the other cerebral vesicles, so that by the seventh month they project behind them. In the floor of each of these hemispheres there occurs a local thickening, which forms the **corpus striatum**, which is continuous behind with the optic thalamus, presently to be described. The surface of the hemisphere is at first smooth, but about the fifth month a sulcus or groove appears in either hemisphere just external to the corpus striatum; this is the **fissure of Sylvius**: subsequently other fissures appear on the surface, three of which are of sufficient depth to cause a projection into the lateral ventricle. These are the **hippocampal fissure**, corresponding to the hippocampus major of the lateral ventricle, the **collateral fissure**, corresponding with the bend of the posterior horn of the ventricle; and the **calcarine fissure**, corresponding with the projection of the calcar avis.

The remainder of the first vesicle and the second, as we have seen, form the third ventricle, in its normal walls a thickening takes place, which forms the **optic thalamus**. From the floor of this ventricle a hollow protrusion passes downward, and is intimately connected with a diverticulum from the stomodeaum, to form part of the **pituitary body** (*hypophysis cerebri*) (Figs. 553, 554, and 555). The greater part of the roof of the third ventricle is very thin, and with the pia mater
forms the velum interpositum; from its posterior part an outgrowth of cells forms the pineal body (epiphysis cerebri). Where the cerebral hemispheres are not separated in the middle line by the falx, in front and for some distance backward over the roof of the third ventricle their mesial surfaces come in contact, and to a certain extent fuse together, leaving, however, a small portion where no union takes place, and thus a slit-like cavity is left; this is termed the fifth ventricle, though it will be at once seen that its development is quite different from that of the other ventricles. Its lateral walls form the septum lucidum. The roof of this cavity becomes thickened, and nerve-fibres pass across from the one hemisphere to the other to form the corpus callosum, while in its floor longitudinal fibres are developed to form the fornix.

The third vesicle, the cavity of which forms the iter a tertio ad quartum ventriculum, develops in its roof four well-marked thickenings, which together form the corpora quadrigemina, while its lateral regions become thickened to form the crura cerebri (Fig. 555).

The dorsal surface of the fourth vesicle forms the covering of the fourth ventricle, and in it a thickening occurs which is developed into the cerebellum; its ventral and lateral regions form the pons (Fig. 555).

In the fifth vesicle the lateral parts increase and grow downward on each side toward the middle line, forming the medulla, while the dorsal surface assists in forming the roof of the fourth ventricle.

On making a transverse section of the lower part of the fourth ventricle, the alar and basal laminae, already referred to as being present in the cord, are readily recognized, while the thin roof-plate is seen to be greatly expanded laterally. The dorsal part of the alar lamina becomes folded outward and downward, form-
ing what is termed the rhomboid lip (Fig. 556). This is at first separated by a groove from the lateral aspect of the alar lamina, but ultimately fuses with it. As the central canal of the cord opens out to form the fourth ventricle, the alar and basal laminae come to occupy the floor of the ventricle—the basal lamina lying nearest the mesial plane.

The Communications of the Parts of the Brain.—In the posterior fossa of the cranium lies the medulla oblongata, the pons Varolii, and the cerebellum, and between these structures and the cerebrum is the tentorium cerebelli. The pons, medulla, and cerebellum surround the fourth ventricle. The greater portion of the fibres of the medulla are continued into the pons, but some fibres from the dorsal aspect of the medulla (the restiform bodies) pass into the cerebellum and become the inferior cerebellar peduncles (Fig. 557). On each side of the pons a thick strand of transverse fibres passes to the cerebellum. These strands are the middle cerebellar peduncles (Fig. 557).

The cerebral hemispheres are joined together by the corpus callosum, a commissure lying within the depths of the great longitudinal fissure. Between and beneath the cerebral hemispheres is the inter-brain (thalamencephalon), composed chiefly of the optic thalami. In the interior of each hemisphere is a space called
the lateral ventricle. Between the optic thalami is the third ventricle. The foramen of Monroe connects the third ventricle with the lateral ventricles.

The mid-brain connects the cerebrum with the pons, medulla, and cerebellum. It is composed of the crus cerebri, which join together the pons and the cerebrum; the corpora quadrigemina, and the superior cerebellar peduncles (Fig. 557), which connect together the cerebrum and the cerebellum. In the mid-brain the aqueduct of Sylvius joins the third ventricle and the fourth ventricle.

General Considerations and Divisions.—For the purposes of description the brain may be divided into five parts, as follows: (1) the two cerebral hemispheres; (2) the inter-brain (thalamencephalon); (3) the mid-brain (mesencephalon); the hind-brain (rhombencephalon), which includes (4) the pons Varolii and cerebellum; and (5) the medulla oblongata. If the student will refer to the section on the Development of the Brain he will find that these five portions correspond fairly accurately to the five secondary cerebral vesicles, of which the brain at an early period of embryonal life consisted; the prosencephalon, or first vesicle, by means of a protrusion from its front part on either side, forms the cerebral hemispheres and the lateral ventricles; the remainder of the prosencephalon, together with the second vesicle, the thalamencephalon, form the inter-brain and third ventricle; the third vesicle, the mesencephalon, forms the mid-brain, or that portion which connects the inter-brain and hemispheres above with the pons Varolii below, and the cavity of the vesicle forms the aqueduct of Sylvius, or iter a tertio ad quartum ventriculum; the fourth vesicle, the metencephalon, becomes the future pons Varolii and cerebellum, and its cavity forms the upper half of the fourth ventricle; and, finally, the fifth vesicle, the myelencephalon, develops into the medulla oblongata, and its cavity forms the lower half of the fourth ventricle. It will thus be seen that the five divisions of the encephalon mentioned above correspond to the five secondary cerebral vesicles, with the exception of the first two, which together form the cerebral hemispheres and the inter-brain. In consequence of this these two portions of the brain are sometimes grouped together as the cerebrum.

I. The Hemispheres of the Cerebrum (Hemisphaeria Cerebri).

General Considerations.—The two hemispheres constitute the largest portion of the encephalon, and, together with the parts derived from the inter-brain (thalamencephalon) form what is called by some writers the fore-brain (prosencephalon). They occupy the whole of the vault of the skull, and consist of a central cavity, in either hemisphere, surrounded by exceedingly thick and convoluted walls of nervous tissue. The under surface or base of the cerebrum is of an irregular form, resting in front on the anterior and middle fosse of the skull and behind upon the tentorium cerebelli. The upper surface is of an ovoid form, broader behind than in front and convex in general outline. The frontal pole (polus frontalis) is the most prominent portion of the anterior end of the hemisphere. The most prominent portion of the posterior end is the occipital pole (polus occipitalis). The most prominent part of the temporal lobe below the fissure of Sylvius is the temporal pole (polus temporalis). The upper surface is divided into two lateral halves or hemispheres, the right and left, by the great longitudinal fissure (fissura longitudinalis cerebri), which extends throughout the entire length of the cerebrum in the middle line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the corpus callosum, which connects the two hemispheres together.

The Constituent Parts of the Hemisphere.—The hemisphere is composed of three distinct parts: the brain-mantle (pallium), the chief mass of the hemisphere; the olfactory brain or lobe (rhinencephalon), composed of the olfactory
bulb, anterior perforated space, a portion of the uncinate gyrus, the hippocampus, the septum lucidum, etc., and the corpus striatum.

The Surface of the Cerebrum.—Each hemisphere presents an outer convex surface (facies convexa cerebri), filling the concavity of the corresponding half of the vault of the cranium; an inner, flattened surface (facies medialis cerebri), which is vertical and directed toward the corresponding surface of the opposite hemisphere (the two inner surfaces forming the sides of the longitudinal fissure); and an under surface or base (basis cerebri), of irregular form, which rests in front on the anterior and middle fossae of the base of the skull, and behind upon the tentorium cerebelli. The hemispheres are composed of an outer stratum of gray matter (substantia grisea), called the cortical substance or the cerebral cortex, and in the interior of a mass of white matter (substantia alba) called the medullary centre. The cortex is thrown into a number of creases or infoldings, which are termed fissures and sulci (sulci cerebri), and these separate the surface into a number of irregular eminences, named convolutions or gyri (gyri cerebri).

The infoldings or creases are of two kinds, complete fissures and incomplete fissures or sulci. The complete fissures (fissurae) are of large size, and appear early in fetal life; they are few in number, nearly constant in their arrangement, and are produced by infoldings of the entire thickness of the wall of the cerebrum, producing corresponding elevations in the interior of the ventricle, and hence are termed complete fissures. They comprise (a) the hippocampal or dentate fissure; (b) the anterior part of the calcarine fissure; (c) the collateral fissure. The sulci are vastly more numerous than the complete fissures; they are superficial depressions of the gray matter, which is folded inward and only indents the central white substance. They produce no corresponding elevations in the interior of the ventricle, and are therefore spoken of as incomplete fissures. They are fairly constant in their arrangement, and have received names indicative of their position and direction, but at the same time vary, within certain limits, in different individuals. They are similar, without being absolutely identical, on the two sides of the brain. It therefore follows that the gyri or convolutions (gyri cerebri) which lie between these sulci are fairly constant in their general arrangement. The gyri upon the surface are named superficial gyri. Within the sulci, adjacent superficial gyri are joined by deep gyri (gyri profundi). Short gyri, superficial or deep which connect two gyri of greater length are called annectant or transitional gyri (gyri transitiivi).

The number and extent of the convolutions, as well as the depth of the intervening sulci, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as one ascends from the lowest mammalia up to man, where they present a most complex arrangement. Again, in the child, at birth, before the intellectual faculties are exercised, the convolutions are simpler, and the sulci between them shallower, than in the adult. In old age, when the mental faculties have diminished in activity, the gyri and sulci become less prominently marked. By their arrangement the convolutions are adapted to increase the amount of gray matter without occupying much additional space, while they also afford a greater extent of surface for the termination of white fibres in gray matter.

It will be convenient in the first instance to describe the fissure which separates the two hemispheres from each other, and those which divide each hemisphere into its larger divisions.

Fissures and Sulci of the Outer Surface of the Hemispheres. The Longitudinal Fissure (fissura longitudinalis cerebri) (Fig. 560).—This great fissure separates the cerebrum into two hemispheres, and reaches from the front to the back of the organ; it contains a vertical process of the dura mater, the falx cerebri (p. 849). In front and behind the longitudinal fissure extends from the top (dorsal surface) to
the bottom (ventral surface) of the cerebrum, and completely separates the two hemispheres, but its middle portion only separates the hemispheres for about half their vertical extent, the floor of this part of the fissure being formed by the great central white commissure, the corpus callosum (Figs. 567 and 571), which connects the two hemispheres together.

The remaining fissures are situated in one or other of the two hemispheres, with the exception of the transverse fissure, one-half of which is contained in each hemisphere.

**Sylvian Fissure** (*fissura cerebri lateralis* [Sylvii]) (Figs. 558, 561, 565, and 570).—This fissure is a well-marked cleft on the base and side of the hemisphere. Starting at the base of the brain in a depression, the vallecula Sylvii, in which is situated the anterior perforated space (Fig. 570). The fissure passes outward between the frontal and temporal lobes, along the lesser wing of the sphenoid bone to the external surface of the hemisphere. The point at which it reaches the external surface is called the Sylvian point. It here gives off a short anterior horizontal limb (*ramus anterior horizontalis*), which passes forward, and a short ascending or vertical limb (*ramus anterior ascendens*), which passes upward into the inferior frontal convolution. It also gives off the posterior horizontal limb (*ramus posterior*), which is the most distinct of the three branches. The posterior horizontal limb lies under the middle third of the lateral surface of the hemisphere and above the temporal lobe. It passes backward and slightly upward for about two and a half inches and terminates by an upward inflexion in the parietal lobe, which is called the ascending terminal portion. The anterior horizontal and the vertical limbs are separated by the frontal operculum (*pars triangularis*), which is the foot of the inferior frontal convolution. A portion of the same convolution below the anterior limb is called the orbital operculum (*pars orbitalis*). Between the vertical and posterior horizontal limbs is the fronto-parietal operculum (*pars opercularis*).
Limiting Sulcus of Reil (sulcus circularis Reili) (Fig. 566).—If the lips of the posterior horizontal limb of the Sylvian fissure are widely separated, the island of Reil (insula) (Figs. 566 and 568) is seen in the depths, surrounded by the limiting sulcus. The upper or external portion of the sulcus separates the island from the parietal and frontal lobes, the lower or posterior portion from the temporal lobe, and the anterior portion from the frontal lobe.

The Central Sulcus of Rolando or the Fissure of Rolando (sulcus centralis [Rolandi]) (Figs. 558, 559, 561, 565, and 574).—The fissure of Rolando is situated about the middle of the outer surface of the hemisphere, and, coursing obliquely downward and forward, divides the surface of the hemisphere into approximately equal parts. It is between the frontal and parietal lobes. It commences as a rule on the mesial surface of the longitudinal fissure, runs forward a short distance, and ascends to the superior mesial border, which it reaches a little behind its mid-point, that is at a point half an inch behind the middle of a line drawn from the nasal eminence to the external occipital protuberance. It then runs sinuously downward and forward, to terminate a little above the hori-

* Fig. 559.—Sulcus of Rolando fully opened up, so as to exhibit the interlocking gyri and deep annectant gyrus behind it. (Cunningham.)

zontal limb of the fissure of Sylvius, and about half an inch behind the ascending limb of the same fissure. The angle made by the fissure of Rolando and the mesial plane is known as the Rolandic angle, and it varies in the adult between 69 degrees and 74 degrees (Cunningham). It forms two chief curves: the upper or superior curve or genu is concave forward and upward, while the lower or inferior curve or genu has its concavity directed backward. If the lips of the Rolandic fissure are opened, we will see in the depths frontal gyri interlocked with parietal gyri (Fig. 559). Two of these gyri are often fused, and this fused gyrus is named the deep annectant gyrus (Fig. 559).

The Parieto-occipital Sulcus (sulcus occipitoparietalis) (Figs. 558, 562, 564, and 565).—The parieto-occipital sulcus is only seen to a slight extent on the outer surface of the hemisphere, being situated for the most part on its mesial aspect. The portion on the outer surface is called the external parieto-occipital sulcus, to distinguish it from the part continued on to the internal surface, which is termed the internal parieto-occipital sulcus. The external parieto-occipital sulcus commences about midway between the posterior extremity or occipital pole of the brain and the central sulcus of Rolando, and runs downward and outward for about half an inch, and is ended by an arch-shaped convolution (arcus parieto-
THE NERVOUS SYSTEM

occipitalis). The internal parieto-occipital sulcus is vertical in direction, is very distinct, and passes into the calcarine fissure. When its lips are fully separated, deep annectant gyri come into view.

Besides the three fissures which have been discussed, the following must be mentioned (the situation of each is shown in Fig. 561). On the outer surface of the hemisphere there are the three frontal sulci, the sulcus frontalis superior, medius, and inferior. The sulcus paramedialis, the superior and inferior precentral sulci, sulcus diagonalis, the superior and inferior temporal sulci, the superior and inferior post-central sulci, the ramus occipitalis, the sulcus occipitalis transversus,

the ramus horizontalis, the calloso-marginal sulcus, the inferior transverse furrow (Fig. 561). The sulcus interparietalis (of Turner) is a group of four sulci: the sulcus post-centralis inferior, the sulcus post-centralis superior, the ramus horizontalis, and the ramus occipitalis. The first two are usually joined; the last two remain distinct and separate. When the lips of the intraparietal sulcus are widely opened, deep annectant gyri come into view.

The fissures of Sylvius, of Rolando, and the parieto-occipital sulcus divide the external surface of the hemisphere into four lobes: the frontal, the parietal, the occipital, and the temporal lobes. To these must be added (1) the central lobe or island of Reil, which is situated deeply in the Sylvian fissure, and (2) the olfactory

Fig. 560.—The cerebral hemispheres viewed from above. (Spalteholz.)
lobe, which is found at the base of the brain and was formerly described under the name of the olfactory nerve.

The Lobes on the External Surface.—The lobes on the external surface have received their names from the bones of the skull with which they are most nearly in relation, but it must be borne in mind that they do not correspond in shape or limit with the bone after which they are named. The division is, moreover, to a certain extent artificial, as will be seen from the following description. If a line is drawn in continuation of the external parieto-occipital sulcus downward and outward to the lower border of the hemisphere, it will impinge on a slight notch, the pre-occipital notch, and if a second line is prolonged backward from the horizontal part of the fissure of Sylvius to join the first line, the division of the outer surface of the hemisphere into four lobes will be accomplished (Fig. 558). The portion in front of the central sulcus of Rolando is the frontal lobe; that behind the central sulcus of Rolando and above the fissure of Sylvius is the parietal lobe; the portion behind the parieto-occipital sulcus and its imaginary line of continuation to the pre-occipital notch is the occipital lobe; and the part below the fissure of Sylvius and in front of the occipital lobe is the temporal lobe.

The Fissures, Sulci, and Lobes of the Mesial and Tentorial Surfaces.—The mesial surface of the cerebrum can only be fully viewed by dividing the corpus callosum and the structures beneath it longitudinally in the middle line; in order to expose the tentorial surface, the pons Varolii, cerebellum, and medulla must be removed, by division of the crus cerebri on either side. The diagram (Fig. 562) and the section (Fig. 564) show these fissures and sulci. The parts in the centre, below the corpus callosum, belong to the interior of the brain, and will be disregarded for the present, while the lobes and fissures of the remaining portion of the hemisphere are considered. The fissures and sulci are ten in number on each side, in addition to a small part of the fissure of Sylvius, the commencement of which is seen separating the frontal and temporal lobes and the beginning and end of the great longitudinal fissure. These fissures and sulci are named the olfactory

---

![Diagram of the brain showing lobes and fissures](image-url)
sulci, the orbital sulci, the inferior and middle temporal sulci, the occipito-temporal sulci, the calloso-marginal and the internal parieto-occipital sulci, the calcarine, the collateral, and the dentate or hippocampal fissures.

The Olfactory Sulcus (sulcus olfactorius) (Figs. 563 and 566).—The olfactory sulcus is a straight furrow which lodges the olfactory tract and bulb.

The Orbital Sulcus (sulcus orbitalis) (Figs. 563 and 566).—The orbital sulcus is usually shaped somewhat like the letter H, and is then composed of an external limb (sulcus orbitalis externus), an internal limb (sulcus orbitalis internus), and a transverse portion (sulcus orbitalis transversus). The parts of the orbital sulcus are often complicated and irregular, and are sulci rather than parts of a sulcus.

The Inferior Temporal Sulcus (sulcus temporalis inferior).—The inferior temporal sulcus is shown in Fig. 563.

The Occipito-temporal Sulcus (Fig. 563).—The occipito-temporal sulcus is in the tentorial base of the occipital lobe. It is external to the collateral fissure, is not limited purely to the temporal lobe, and bounds the occipito-temporal gyrus externally. It often consists of two or more portions.

---

**Fig. 562.**—The gyri and sulci on the medial aspect of the cerebral hemisphere: r, fissure of Rolando; r.o., rostral sulcus; i.t., insula temporalis. (Cunningham.)

The Calloso-marginal Sulcus (sulcus cingulus) (Figs. 562, 564, and 567).—The calloso-marginal sulcus commences below the anterior extremity of the corpus callosum; it at first runs forward and upward, parallel with the rostrum of the corpus callosum, and, winding round in front of the genu of that body, it continues from before backward, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it ascends to reach the upper margin of the hemisphere, a short distance behind the superior extremity of the fissure of Rolando.

The Internal Parieto-occipital Sulcus (sulcus parietooccipitalis) (Figs. 562, 564, and 567).—The internal parieto-occipital sulcus extends in an oblique direction downward and forward to join the calcarine fissure, on a level with the hinder end of the corpus callosum.

The Calcarine Fissure (fissura calcarina) (Figs. 562, 564, and 567).—The calcarine fissure commences, usually by two branches, close to the posterior extremity of the hemisphere. These soon unite, and the fissure runs nearly horizontally forward, and is joined by the parieto-occipital fissure, and continues as far as the
posterior extremity of the corpus callosum, a little below the level of which it terminates in the limbic lobe. Its anterior part causes the prominence in the interior of the brain known as the hippocampus minor or calcar avis.

**The Collateral Fissure** *(fissura collateralis)* (Figs. 562, 563, 564, and 567).—The collateral fissure is situated on the tentorial surface, below and external to the preceding, being separated from it by the subcollateral or uncinate gyrus. It runs forward, from the posterior extremity of the brain, nearly as far as the tip of the temporal lobe. It lies below the posterior and descending horns of the lateral ventricle, and its middle part causes the prominence in the interior of the brain known as the eminentia collateralis.

**The Dentate or Hippocampal Fissure** *(fissura hippocampi)* (Figs. 563, 564, and 567).—The dentate or hippocampal fissure commences immediately behind

![Diagram of the brain](image)

Fig. 563.—Gyri and sulci on the tentorial and orbital aspects of the cerebral hemisphere. (Cunningham.)

the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the hippocampal gyrus. It causes the prominence of the hippocampus major in the descending horn of the lateral ventricle.

In addition to these fissures, which are constant, there is frequently an irregular broken fissure, which is sometimes an independent sulcus, but which often appears to be a continuation backward of the posterior part of the calloso-marginal fissure, before it ascends to reach the upper edge of the hemisphere. This has been termed the post-limbic fissure (Fig. 562). The fissures of the internal and tentorial surfaces map off portions of the hemisphere, which form parts of the lobes found on the external surfaces. That portion which lies in front and above the calloso-marginal fissure belongs almost entirely to the frontal lobe; its posterior extremity, which extends for a short distance behind the upper end of the
fissure of Rolando, forms a small part of the parietal lobe; that portion which lies above the internal parieto-occipital fissure and behind the calloso-marginal fissure forms a part of the parietal lobe; that between the parieto-occipital fissure above and the calcarine fissure below is a portion of the occipital lobe; and all the region below the calcarine fissure behind and the collateral fissure in front belongs to the temporal lobe. The remainder of the mesial and tentorial surfaces of the hemisphere constitute what Broca termed the limbic lobe, which is subsequently referred to (p. 878).

The surface of the hemisphere has thus been divided by large sulci and fissures into its different parts—viz., the frontal, the parietal, the occipital, the temporal, the limbic, the olfactory lobes, and the island of Reil. Each of these lobes is further subdivided into convolutions or gyri by smaller fissures, which, though less constant in their arrangement than the larger fissures, have a fairly definite course.

1. The Frontal Lobe (lobus frontalis) (Figs. 558, 561, 562, 563, 564, 565, and 566).

—It is the largest of the lobes of the cerebrum. Its outer surface is bounded behind by the central sulcus of Rolando and below by the posterior horizontal limb of the fissure of Sylvius. On the orbital surface the fissure of Sylvius bounds it posteriorly. On the mesial surface it is bounded by the calloso-marginal sulcus.

External Surface.—On its external surface the frontal lobe presents three sulci and four gyri or convolutions. The sulci are the precentral, the superior frontal, and the inferior frontal.

The Precentral Sulcus (sulcus praecentralis) is divided into two parts: The inferior precentral sulcus (sulcus praecentralis inferior) is composed of two parts (Figs. 561 and 565): one part (the vertical) is placed before the Rolandic fissure; the other part (the horizontal) passes upward and to the front into the middle frontal convolution. The superior precentral sulcus (sulcus praecentralis superior) is vertical in direction and is placed in front of the upper part of the Rolandic fissure. The other frontal sulci are shown in the diagrams.

The ascending frontal convolution or precentral gyrus (gyrus centralis anterior or gyrus frontalis ascendens) (Figs. 561 and 565), one of the chief motor areas of the
THE HEMISPHERES OF THE CEREBRUM

THE HEMISPHERES OF THE CEREBRUM

873
cortex, is a simple convolution, and is limited in front by the precentral sulcus and behind by the fissure of Rolando. It extends from the upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below. From it two sulci, the superior and inferior frontal sulci (sulcus frontalis superior and sulcus frontalis inferior), run forward and downward, and divide the remainder of the outer surface of the lobe into three parallel principal convolutions, named respectively the superior, middle, and inferior frontal convolutions (Figs. 561 and 565).

The superior or first frontal convolution (gyrus frontalis superior) (Figs. 561 and 565) is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the greater part of the marginal convolution (Figs. 562, 564, and 567), and in front on to the orbital surface, forming the internal orbital convolution (Figs. 563 and 566). It is usually more or less completely subdivided into two (pars superior and pars inferior) by several depressions of trivial length, the aggregation being called by Cunningham the sulcus paramedialis. It is frequently interrupted and broken into several parts by bridging convolutions.

The second or middle frontal convolution (gyrus frontalis medius) (Figs. 561 and 565) is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus on to the orbital surface of the lobe, where it forms the anterior orbital convolution (Figs. 563 and 566). The middle frontal convolution is frequently subdivided into two (pars superior and pars inferior) by a sagitally directed sulcus, the sulcus frontalis medius of Eberstaller.

The third or inferior frontal convolution (gyrus frontalis inferior) (Figs. 561 and 565) is situated below the inferior frontal sulcus, and extends forward from the lower part of the precentral sulcus, on to the under surface of the lobe, where it forms the pos-
terior orbital convolutions (Figs. 563 and 566). The inferior frontal convolution is subdivided by the anterior and ascending limbs of the fissure of Sylvius into three parts—viz.: (1) anterior part or the orbital operculum (pars orbitalis), below the anterior limb of the fissure of Sylvius; (2) middle part or "cap" of Broca or the frontal operculum (pars triangularis), between the anterior horizontal and the vertical limbs of the fissure of Sylvius; and (3) posterior part or the fronto-parietal operculum (pars basilaris), behind the posterior horizontal and vertical limbs of the fissure of Sylvius. In the basilar part is the sulcus diagonalis (d in Fig. 561). The left inferior frontal convolution is, as a rule, more highly developed than the right, and is named the convolution of Broca, from the fact that in 1861 Broca declared that it was the centre for speech. It is now known that the region of speech comprises the posterior part of the inferior frontal convolution and the fronto-parietal operculum.

**Fig. 566.**—Convolutions and sulci on the under surface of the anterior lobe.

**Under Surface** (Figs. 563 and 566).—The under surface of the frontal lobe rests on the orbital plate of the frontal bone, and is sometimes named the orbital lobe. It is divided into three convolutions by a well-marked sulcus, the orbital or tri-radiate sulcus (sulci orbitales). These convolutions are named, from their position, the internal, anterior, and posterior orbital convolutions, and are the continuations respectively of the superior, middle, and inferior frontal convolutions of the external surface. The internal orbital convolution presents a well-marked antero-posterior groove or sulcus, the olfactory sulcus (sulcus olfactorius), for the olfactory bulb and tract; and the portion internal to this is named the gyrus rectus, and is continuous with the marginal gyrus, presently to be described.

**Mesial or Internal Surface** (Figs. 562 and 567).—The mesial or internal surface of the frontal lobe is occupied by a single curved convolution, which from its
situation is termed the marginal gyrus (*gyrus marginalis*). It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the mesial surface of the orbital lobe, where it is continuous with the internal orbital convolution; it then ascends, and runs backward to the point where the calloso-marginal fissure turns upward to reach the superior border of the hemisphere. An oval portion at the posterior part of this convolution is sometimes marked off by a vertical fissure, and is distinguished as the paracentral lobule (*lobulus paracentralis*), because it is continuous with the convolutions in front and behind the central fissure or fissure of Rolando. In the anterior portion of the marginal gyrus are two sulci named the sulci rostrales.

2. **The Parietal Lobe** (*lobus parietalis*) (Figs. 558, 561, 562, 564, 565, and 567).—This lobe includes a considerable portion of the surface of the hemisphere, and it also occupies the portion of the mesial surface known as the quadrat lobule or cuneus. It is bounded in front by the central sulcus of Rolando. Posteriorly it is partly separated from the occipital lobe by the external parieto-occipital sulcus. Below it is partly limited by the posterior horizontal limb of the fissure of Sylvius.

**External Surface.**—On its external surface the parietal lobe presents for examination one sulcus (which is divided into four parts) and three convolutions.

The **Intraparietal Sulcus of Turner** (*sulcus intraparietalis*) (Figs. 561 and 565); according to Prof. Cunningham, is a group of four sulci—viz., the superior post-central sulcus (*sulcus postcentralis superior*), the inferior post-central sulcus (*sulcus postcentralis inferior*), the horizontal ramus (*ramus horizontalis*), and the occipital ramus (*ramus occipitalis*). The first named lies back of the upper portion of the central sulcus of Rolando; the second lies back of the lower portion of the same sulcus. In front of the post-central sulci is the ascending parietal (post-central) convolution (*gyrus centralis posterior*). The superior and inferior post-central sulci are usually continuous. The upper end of the inferior post-central sulcus is prolonged upward and backward as the ramus horizontalis between the superior and inferior parietal gyri. The ramus occipitalis may or may not be joined to the ramus horizontalis. It is the external boundary of the arcus parieto-occipitalis.
The ascending parietal convolution or the post-central gyrus (gyrus ascendens parietalis or gyrus postcentralis) (Figs. 561 and 565) is usually regarded as one of the chief motor areas of the cortex, although Mills, Sherrington and others are of the opinion that the motor areas are all in front of the central sulcus of Roland. The ascending parietal convolution is bounded in front by the central sulcus of Rolando, behind by the superior and inferior post-central sulci. It extends from the great longitudinal fissure above to the posterior horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also, sometimes, above the termination of the central sulcus of Rolando.

The superior parietal convolution (lobulus parietalis superior) (Figs. 561 and 565), still regarded by some as a part of the motor area of the cortex, is bounded in front by the superior post-central sulcus, which lies between it and the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is joined to the occipital lobe by a narrow convolution, the first annexant gyrus (arcus parietooccipitalis); below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above, it is continuous on the inner surface of the hemisphere with the quadrate lobe.

The inferior parietal convolution (lobulus parietalis inferior) (Figs. 561 and 565) is that portion of the parietal lobe which is situated between the ascending portion of the intraparietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is divided into three convolutions: the supramarginal, the angular, and the post-parietal. One, the supramarginal convolution (gyrus supramarginalis), lies behind the ascending part of the intraparietal sulcus and above the horizontal limb of the fissure of Sylvius, over the extremity of which it arches. It is connected in front with the ascending parietal convolution below the intraparietal sulcus, and behind with the first or superior temporal convolution around the posterior extremity of the fissure of Sylvius (Fig. 561). The angular convolution or the angular gyrus (gyrus angularis) is united anteriorly with the foregoing, while posteriorly it is continuous with the middle or second temporal convolution by a process which curves around the superior temporal or parallel sulcus (Fig. 561). The post-parietal convolution or the second annexant gyrus passes around the posterior end of the middle temporal convolution and into the inferior temporal convolution. It joins the inferior parietal convolution to the occipital lobe.

The Internal or Mesial Surface (Figs. 562 and 564).—The internal or mesial surface of the parietal lobe is continuous with the external surface over the upper edge of the hemisphere. It is of small size, and forms one square-shaped convolution, which from its shape is termed the quadrate lobe. From its situation above the cuneate lobe it is named the precuneus (praeconvexus). The post-limbic sulcus imperfectly separates the precuneus from the limbic lobe.

3. The Occipital Lobe (lobus occipitalis) (Figs. 558, 561, 562, 563, 564, 565, and 567).—The occipital lobe is indefinitely separated from the temporal and parietal lobes. It is defined by Cunningham as the portion of "the hemisphere which encloses the posterior horn of the lateral ventricle." In form it is pyramidal, and it possesses an apex, the occipital pole (polus occipitalis), and three surfaces. The inferior surface is directly continuous with the temporal and limbic lobes. On the outer surface the external parieto-occipital fissure partly separates it from the parietal lobe. On the mesial surface the internal parieto-occipital fissure separates it from the precuneus.

External Surface (Figs. 561 and 565).—The occipital lobe is divided on its external surface into three convolutions by two indistinct sulci, the superior and middle occipital sulci (sulcus occipitalis transversus and sulcus occipitalis lateralis). They are directed backward across the lobe, being frequently small and ill marked; the superior is sometimes continuous with the horizontal portion of the intraparietal sulcus.
The **superior occipital convolution** (*gyrus occipitalis superior*) is situated above the superior sulcus, and is connected to the superior parietal convolution by the **first annectant gyrus**.

The **middle occipital convolution** (*gyrus occipitalis medius*) is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the **second annectant gyrus**, and to the middle temporal convolution by the **third annectant gyrus**.

The **inferior occipital convolution** (*gyrus occipitalis inferior*) is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal convolution on the under surface of the hemisphere by an inconstant sulcus, the **inferior occipital sulcus** (*sulcus occipitalis inferior*). The inferior occipital convolution is connected to the inferior temporal convolution by the **fourth annectant gyrus**.

**Internal or Mesial Surface** (Figs. 562, 564, and 567).—The internal or mesial surface of the occipital lobe presents a triangular convolution, which is known as the **cuneate lobule** (*cuneus*). It is situated between the internal parieto-occipital sulcus and the calcarine fissure, which, as already mentioned, meet some distance behind the posterior extremity of the corpus callosum.

The **lingual gyrus** or **subcalcarine convolution** (*gyrus lingualis*) is between the calcarine and collateral fissures, and runs forward into the hippocampal portion of the limbic lobe. A portion of the gyrus lingualis is on the mesial aspect and a portion on the inferior aspect of the occipital lobe (Fig. 563).

**Inferior Surface** (Fig. 563).—The inferior or tentorial surface of the occipital lobe possesses one convolution, the **occipito-temporal gyrus**, which is continuous with the temporal lobe and the **limbic lobe** (p. 878), and is bounded externally by the occipito-temporal sulcus.

The centre for visual memory is in the external surface of the occipital lobe and the angular gyrus.

4. **The Temporal Lobe** (*lobus temporalis*) (Figs. 558, 561, 562, 563, 564, 565, and 567).—The temporal lobe is sometimes called the **temporo-sphenoidal lobe**. This lobe lies behind the junction point and below the posterior horizontal limb of the Sylvian fissure. On its inferior (tentorial) surface the collateral fissure separates it from the hippocampal portion of the limbic lobe. The apex of the temporal lobe projects in front of the Sylvian junction. The lobe presents an outer and an inferior surface.

**Outer Surface** (Figs. 561 and 565).—The outer surface is subdivided by two sulci, named respectively the **first** and **second temporal sulci**.

The **First Temporal Sulcus** (*sulcus temporalis superior*) is well marked, and runs from before backward through the temporal lobe parallel with, but some little distance below, the posterior horizontal limb of the fissure of Sylvius; hence it is often termed the **parallel sulcus**.

The **Second Temporal Sulcus** (*sulcus temporalis medius*) takes the same direction as the first, but is situated at a lower level, and is often interrupted by one or more bridging convolutions. These two sulci subdivide this surface of the temporal lobe into three convolutions.

The **first or superior temporal convolution** (*gyrus temporalis superior*) is situated between the posterior horizontal limb of the fissure of Sylvius and the first temporal sulcus, and is continuous behind with the supramarginal convolution.

The **second or middle temporal convolution** (*gyrus temporalis medius*) lies between the first and second temporal sulci, and is continued behind into the angular and middle occipital convolutions.

The **third or inferior temporal convolution** (*gyrus temporalis inferior*) is placed below the second temporal sulcus; it is connected posteriorly with the inferior occipital convolution, and is also prolonged on to the under or tentorial surface
of the temporal lobe (Fig. 563), where it is limited internally by the third temporal sulcus, about to be described.

Inferior Surface (Fig. 563).—The inferior or tentorial surface presents two fissures—viz., the third temporal sulcus and the collateral fissure—the latter fissure has already been described (p. 871).

The Third Temporal Sulcus (sulcus temporalis inferior) extends from near the occipital pole behind to near the anterior extremity of the temporal lobe in front, but is, however, frequently subdivided by bridging gyri.

The convolution on the inferior surface is the fourth temporal or subcollateral or the occipito-temporal convolution. It is situated between the third temporal sulcus and the collateral fissure.

5. The Central Lobe or Island of Reil (Insula) (Figs. 566, 568, 576, and 577).—The central lobe or island of Reil lies deeply in the Sylvian fissure, and can only be seen when the lips of that fissure are widely separated, since it is overlapped and hidden by the convolutions which bound the fissure. These convolutions are termed the opercula of the insula (opercula insulae) (operculum, a lid); they are separated from each other by the three limbs of the Sylvian fissure, and are named the orbital, frontal, fronto-parietal, and temporal opercula (p. 866). The insula is almost surrounded by a deep limiting sulcus, the limiting sulcus of Reil (sulcus circularis Reili) (Figs. 566 and p. 867), which separates it from the frontal, parietal, and temporal lobes. When the opercula have been removed, the insula presents the form of a triangular eminence; its apex is directed downward and inward toward the anterior perforated space, and is continuous in front with the posterior orbital convolution. At the apex of the insula the limiting sulcus does not exist, and the gray matter passes into the anterior perforated space. This point is called the limen insulae. The insula is continuous behind with the hippocampal convolution. It is divided into a pre-central and a post-central lobe by the sulcus centralis, which runs backward and upward from the apex of the insula. The pre-central lobe is further subdivided by shallow sulci into three or four short convolutions, the gyri breves insulae, while the post-central lobe is named the gyrus longus insulae, and is often bifurcated at its upper extremity. The gray matter of the insula is continuous with that of the different opercula, while its mesial surface corresponds with the external surface of lenticular nucleus of the corpus striatum, from which it is separated by the external capsule and claustrum.

6. Limbic Lobe (Figs. 564 and 569).—The term limbic lobe or grande lobe limbique was introduced by Broca in 1878, and under it he included two convolutions—viz., the callosai and hippocampal convolutions, which together arch around

![Image](https://via.placeholder.com/150)
the corpus callosum and the hippocampal fissure. These are separated on the morphological ground that they are well developed in animals possessing a keen sense of smell (osmotic animals), such as the dog and fox. To the lobe thus defined the following parts must be added—viz., the laminae of the septum lucidum, together with the fornix and its fimbriae, which may be regarded as forming an inner or deep arch; the peduncles and longitudinal striae of the corpus callosum, together with the gyrus dentatus, which form a middle arch, while the outer arch is constituted by the callosal and hippocampal convolutions; the first two arches are separated from each other by the corpus callosum.

Convolutions of the Limbic Lobe.—
(1) The callosal convolution ( gyrus fornicatus or gyrus cinguli) (Figs. 562 and 567) is an arch-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like sulcus, the callosal sulcus (sulcus corporis callosi). It commences below the rostrum of the corpus callosum. The inner root of the olfactory tract enters the beginning of the convolution. The callosal convolution curves around in front of the genu, extends along the upper surface of the body, and finally turns downward behind the splenium, where it becomes narrow because the calcine fissure cuts it. The narrow portion is the isthmus (isthmus gyri fornicati). The isthmus connects the callosal convolution with the gyrus hippocampi. The callosal convolution is separated from the marginal convolution by the callosal-marginal sulcus, from the precuneus by the post-limbic sulcus, and from the lingual gyrus by the anterior portion of the calcine fissure.

(2) The hippocampal convolution ( gyrus hippocampi) (Figs. 562 and 563) is bounded above by the hippocampal or dentate fissure, and below by the anterior part of the collateral fissure. Behind, it is continuous superiorly, through the isthmus, with the callosal convolution, and inferiorly with the subcalcarine or lingual convolution. Its anterior extremity is recurved in the form of a hook, and is named the uncinate convolution or uncus (Fig. 567). Running in the substance of the callosal and hippocampal convolutions, and connecting them together, is a tract of arched fibres, named the fillet of the gyrus fornicatus or the cingulum. The outer root of the olfactory tract passes into the anterior extremity of the hippocampal convolution, and the inner root into the commencement of the callosal convolution, so that these two convolutions, with the addition of the olfactory tract, present a racquet-like appearance—the olfactory tract constituting the handle and the two convolutions the circumference of the blade.

(3) The dentate convolution ( gyrus dentatus) (Figs. 562 and 581), also called the dentate fascia (fascia dentata hippocampi). It is situated above the gyrus hippocampi, from which it is separated by the hippocampal or dentate fissure ( fissura hippocampi) (Figs. 562, 564, and 567). The dentate convolution is covered by the fimbria, a prolongation of the posterior pillar of the fornix, and is a narrow, elongated convolution, the free surface of which presents a notched or toothed appearance, hence its name. Posteriorly it is prolonged as a delicate lamina, the fasiola cinerea, around the splenium of the corpus callosum, and becomes continuous on the upper surface of that body with its mesial and lateral longitudinal striae. Anteriorly it is prolonged into the notch produced by the recurving of the uncus, where it forms a sharp curve; from here it can be traced as a delicate band, the band of Giacomini, over the uncus, on the outer surface of which it is lost.
The remaining structures which contribute to the formation of the limbic lobe will be subsequently described.

7. **The Olfactory Lobe or Rhinencephalon** (*lobus olfactorius*) (Figs. 555 and 569).—The olfactory lobe is situated on the under surface of the frontal lobe. It is rudimentary in man and some other mammals, but in vertebrates generally it is well developed, and consists of a distinct extension of the cerebral hemisphere, enclosing a portion of the anterior horn of the lateral ventricle. In man it is long and slender, and may be described as consisting of two parts, the **anterior** and **posterior olfactory lobules**.

**The Anterior Olfactory Lobule.**—The anterior olfactory lobule is made up of:

1. the **olfactory bulb**;
2. the **olfactory tract**;
3. the **trigonum olfactorium**;
4. the **area of Broca**.

---

(1) The **Olfactory Bulb** (*bulbus olfactorius*) (Fig. 570) is an oval mass of reddish-gray color, which rests on the cribiform plate of the ethmoid bone below and the olfactory sulcus of the orbital surface of the frontal lobe above. It forms the anterior expanded extremity of the olfactory tract. Its under surface receives the olfactory nerves, which pass upward through the cribiform plate from the olfactory region of the nose. Its minute structure will be subsequently described.

(2) The **Olfactory Tract** (*tractus olfactorius*) (Fig. 570), often called the **olfactory nerve** or **first cranial nerve**, is a band of white matter, triangular on section, the apex being directed upward. It lies in the olfactory sulcus on the under surface of the frontal lobe. Traced backward, it is seen to divide into two roots, an outer
and an inner. Some have called the olfactory tubercle a middle root. The outer root passes across the outer part of the anterior perforated space to the nucleus amygdalae and the anterior part of the gyrus hippocampi. The inner root turns sharply inward, and ends partly in Broca’s area and partly in the callosal convolution; in other words, the inner root is continuous with one extremity and the outer root with the other extremity of the limbic lobe (Fig. 569).

(3) The Trigonum Olfactorium or Olfactory Tubercle is situated between the diverging roots of the olfactory tract, and is sometimes described at the middle or gray root of the tract. It is part of an area of gray matter, which forms the base of the anterior olfactory lobule; another portion of it is termed (4) the area of Broca (area parolfactoria), the portion of gray matter between the internal root and the peduncle of the corpus callosum; and a third portion, of no special significance, is situated external to the outer root of the olfactory tract. This area of gray matter is bounded internally and posteriorly by a sulcus, the fissura prima (sulcus parolfactorius posterior), which separates it from the peduncle of the corpus callosum and from the posterior olfactory lobule. The area of Broca is continuous with the gyrus fornicatus, and receives fibres from the inner or mesial root.

The Posterior Olfactory Lobule.—The posterior olfactory lobule corresponds to the portion of the hemisphere called the anterior perforated space (locus perforatus anticus or substantia perforata anterior) (Figs. 566 and 570). It is marked off from the anterior lobule by the sulcus parolfactorius posterior, and is situated at the commencement of the fissure of Sylvius. Internally, it is bounded by the peduncle of the corpus callosum, and is continuous with the lamina cinerea. Posteriorly it is bounded by the optic tract, and is partially concealed by the temporal lobe which overlaps it. It has received the name of anterior perforated space from its being perforated by numerous openings, which transmit blood-vessels to the interior of the brain, and it corresponds to the under surface of the lenticular nucleus.

Under Surface or Base of the Encephalon (facies basalis encephali) (Fig. 570).—Having considered the surface of the hemispheres, the student should direct his attention to the base of the brain, before commencing the study of the component parts which make up the two hemispheres.

The base of the brain presents for examination the under surfaces of the frontal and temporal lobes; the structures contained in the interpeduncular space, with the crura cerebri or cerebral peduncles; the under surfaces of the pons Varolii, cerebellum, and medulla oblongata; and the superficial origins of the cranial nerves.

The various objects exposed to view (with the exception of the superficial origins of the cranial nerves, which will be considered in another section), in the middle line and on either side of the middle line, are here arranged in the order they are met with from before backward.

**In the Middle Line.**

- Longitudinal fissure.
- Rostrum and peduncles of corpus callosum.
- Lamina cinerea.
- Optic commissure.
- Tuber cinereum.
- Infundibulum.
- Pituitary body.
- Corpora albicantia.
- Posterior perforated space.
- Pons Varolii.
- Medulla oblongata.

**On Each Side of the Middle Line.**

- Frontal lobe.
- Olfactory lobe.
- The anterior perforated space.
- Fissure of Sylvius.
- Optic tracts.
- Crura cerebri.
- Temporal lobe.
- Hemisphere of cerebellum.
The Longitudinal Fissure (fissura longitudinalis cerebri) (p. 865).—The longitudinal fissure partially separates the two hemispheres from each other. It divides completely the anterior portions of the two frontal lobes; and on raising the cerebellum and pons it will be seen to separate completely the two occipital lobes; of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate part of the fissure is filled up by the great transverse band of white matter, the corpus callosum. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

The Corpus Callosum.—The corpus callosum, the transverse commissure which joins the two cerebral hemispheres, is described on p. 886. It terminates at the base of the brain by a concave margin, which is connected with the tuber cinereum through the intervention of a thin layer of gray substance, the lamina cinerea. This may be exposed by gently raising and drawing back the optic commissure. A white band may be observed on each side, passing backward from the under surface of the corpus callosum, across the posterior margin of the anterior perforated space to the hippocampal gyrus, where it meets the corresponding outer root of the olfactory tract; this band is called the peduncle of the corpus callosum or the gyrus subcallosus (pedunculus corporis callosi). The band may be traced upward around the genu to become continuous with the striae longitudinales on its upper surface. Laterally, this portion of the corpus callosum extends into the frontal lobe.

The Lamina Cinerea.—The lamina cinerea is a thin layer of gray substance, extending upward in the anterior portion of the great longitudinal fissure from the optic commissure to join the rostrum of the corpus callosum. It is continuous on each side with the gray matter of the anterior perforated space, and forms the anterior part of the inferior boundary of the third ventricle. The portion of the lamina cinerea which is turned upward is called the lamina terminalis.

The Optic Commissure or Optic Chiasma (chiasma optieum).—The optic commissure is situated in the middle line, immediately in front of the tuber cinereum and below the lamina cinerea; that is to say, the commissure is superficial to the lamina in the order of dissection when the base is uppermost. It is the point of junction between the two optic tracts, and will be described with the cranial nerves. Immediately behind the diverging optic tracts, and between them and the peduncles of the cerebrum (crura cerebri or pedunculi cerebri), is a lozenge-shaped interval, the interpeduncular space (fossu interpeduncularis [Tarinii]). The posterior recess (recessus posterior) of this space passes for a little way underneath the anterior margin of the pons; the anterior recess (recessus anterior) passes between the corpora albicantia. The floor of the interpeduncular space is the substantia perforata posterior, and in the space are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The Tuber Cinereum.—The tuber cinereum is an eminence of gray matter, situated between the optic tracts, and extending from the corpora albicantia to the optic commissure, to which it is attached; it is connected with the surrounding parts of the cerebrum, forms part of the floor of the third ventricle, and is continuous with the gray substance in that cavity. From the middle of its under surface a conical tubular process of gray matter, about two lines in length, is continued downward and forward to be attached to the posterior lobe of the pituitary body. This is the infundibulum, and its canal, which is funnel-shaped, communicates with the third ventricle.

The Pituitary Body (hypophysis cerebri).—The pituitary body is a small, reddish-gray, vascular mass, weighing from five to ten grains, and of an oval form, situated in the sella turcica, where it is retained by a process of dura mater, named the diaphragma sellae (Fig. 544). This process of the dura covers in the sella turcica,
and has a small hole in its centre through which the infundibulum passes, the foramen diaphragmatis sellae (Fig. 544).

**Structure.**—The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior and the larger is of an oblong form, and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The anterior lobe, of a dark, reddish-brown color, is developed from the epiblast of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted tubules, lined by epithelium and united together by a very vascular connective tissue. The epithelium is columnar and occasionally ciliated. The alveoli sometimes contain a colloid material, similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatic and capillary blood-vessels. The posterior lobe is developed as an outgrowth from the embryonic brain, and during foetal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, and consists of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment. In the lower animals the two lobes are quite distinct, and it is only in the mammalia that they become fused together. The pituitary body is believed to be a ductless gland, which furnishes an internal secretion. In many cases of acromegaly the gland is enlarged or otherwise diseased.

**The Corpora Albicantia or Corpora Mamillaria.**—The corpora albicantia or mamillaria are two small, round, white masses, each about the size of a pea, placed side by side immediately behind the tuber cinereum, and connected with each other across the mesial plane. They are mainly formed by the anterior crura or pillars of the fornix, which, after descending to the base of the brain, are twisted upon themselves to form loops, and constitute the white covering of the corpora albicantia. A second fasciculus, the bundle of Vicq d’Azyn (fasciculus thalamomamillaris) (Figs. 574 and 586), converges from the optic thalamus, and enters the anterior part of each body on its dorso-mesial surface. The corpora albicantia are composed externally of white substance, and internally of gray matter; the nerve-cells of the gray matter are arranged in two sets, inner and outer, the cells of the former set being the smaller. Each corpus is connected to the tegmentum by a small bundle of fibres, the peduncle of the mamillary body (pedunculus corporis mamillaris) (Fig. 586). At an early period of foetal life the corpora albicantia are blended together into one large mass, but become separated about the seventh month. In most vertebrates there is only one median corpus albicans.

**The Posterior Perforated Space or Lamina or the Pons Tarini** (locus perforatus posticus, substantia perforata posterior).—The posterior perforated space corresponds to a whitish-gray fossa placed between the corpora albicantia in front, the pons Varolii behind, and the crus cerebri on either side. It is in reality a visible portion of the substantia nigra and forms the floor of the interpeduncular fossa. It forms the posterior part of the floor of the third ventricle, and is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries. Slender white bands are observed in some subjects coming from the gray matter of the posterior perforated space, passing around the crura cerebri, and entering into the pons Varolii. The bands bear the name of the taenia pontis.

**The Pons Varolii** (p. 922).—The pons Varolii is situated immediately behind the two crura of the cerebrum. It consists of a broad band of white fibres, which pass transversely from one cerebellar hemisphere to the other; the band becoming
narrower as it enters the cerebellum. In the middle line on its under surface a narrow groove runs from before backward and accommodates the basilar artery.

**The Medulla Oblongata, Medulla Spinalis or Bulb** (p. 938).—The medulla oblongata emerges from the posterior border of the pons Varolii; it is pyramidal in form, and is continuous below with the cervical portion of the spinal cord. It is marked on its ventral surface by a median fissure, continuous below with the anterior median fissure of the cord, and on either side by secondary fissures and columns, which will be described in the sequel.

**The Frontal Lobe.**—The under surface of the frontal lobe, sometimes named the orbital lobe, is seen on the anterior part of the base of the brain on either side of the median line. It has already been described (p. 874).

**The Olfactory Lobe** (p. 880).

**The Anterior Perforated Space** (p. 881).

**The Fissure of Sylvius** (*fissura lateralis cerebri*).—The fissure of Sylvius at the base of the brain separates the frontal from the temporal lobe, and lodges the middle cerebral artery. It has also been described (p. 866).

---

![Section of the brain. Made on a level with the corpus callosum.](image)

**The Optic Tracts.**—The optic tracts are well-marked, flattened bands of fibres, which run obliquely across the crus cerebri on either side, and unite anteriorly to form the optic commissure. They will be described in connection with the cranial nerves.

**The Crura Cerebri or the Peduncles of the Cerebrum** (*pedunculi cerebri*) (p. 906).—The crura cerebri are two thick cylindrical bundles of white matter, which appear
in front of the anterior border of the pons, and diverge as they pass forward and outward to enter the under surface of each hemisphere. They compose the chief portion of the mesencephalon. Each crus is about three-quarters of an inch in length, and is about the same in breadth anteriorly, but somewhat less posteriorly. They are marked upon their surface with longitudinal striae, and each is crossed, just before entering the hemisphere, by the fourth nerve and the optic tract, the latter of which is adherent by its upper surface to the peduncle. Each crus is composed of two parts, a superior or dorsal part, and an inferior, ventral, or pedal part. The dorsal part is known as the tegmentum of the crus cerebri (tegmentum), the fibres (p. 908) of which pass up into the region beneath the optic thalamus, a region known as the subthalamic tegmental region. The ventral portion is known as the crista (basis pedunculi), the fibres of which (p. 907) pass up external to the optic thalamus and into the internal capsule. On the surface of the crus are two grooves which mark the separation between the tegmentum and the crista. One groove is on the inner (mesial) surface; it is called the sulcus nervi oculo-motorii, and from it comes the third or motor oculi nerve. The other groove on the outer (lateral) surface is called the sulcus lateralis mesencephali. It passes down into the interval between the superior and middle cerebellar peduncles. From the outer surface of the tegmentum some slender fibres, called the lateral fillet (lemniscus lateralis), pass to the inferior quadrigeminal body. If a transverse section of the crus is made, the substantia nigra is seen between the tegmentum and the crista. It is a band of pigmented gray matter which begins somewhat below the upper margin of the pons and ascends into the subthalamic area.

The Temporal Lobe (Fig. 878).—The under surface of the temporal lobe is visible at the base of the brain, on either side of the crura and the structures contained in the interpeduncular space. It is separated anteriorly from the frontal lobe by the fissure of Sylvius, and behind is limited by the anterior border of the lateral hemispheres of the cerebellum. The fissures and lobes on its surface have already been described (p. 877).

The Hemispheres of the Cerebellum (hemisphaeria cerebelli) (p. 929).—The hemispheres of the cerebellum are situated on either side of the middle line, and cover the occipital lobes of the cerebrum, when viewed from the base. The cerebellum differs much in appearance from the rest of the encephalon, being of a darker color, while its convolutions are smaller and narrower, are arranged like the leaves of a book, and hence are called folia.

General Arrangement of the Parts Composing the Cerebrum.—Each hemisphere, as already stated, consists of a central cavity, the lateral ventricle, surrounded by thick and convoluted walls of nervous tissue.

Interior of the Cerebrum.—If the upper part of either hemisphere is removed with a knife, about half an inch above the level of the corpus callosum, its internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of gray matter, which presents an equal thickness in nearly every part. This white central mass has been called the centrum ovale minus. Its surface is studded with numerous minute red dots (puncta vasculosa), produced by the escape of blood from divided blood-vessels. In inflammation or great congestion of the brain these are very numerous and of a dark color. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed, connecting them at the bottom of the longitudinal fissure; this is the corpus callosum. The margins of the hemispheres which overlap this portion of the brain are called the labii cerebri. Each labium is part of the callosal convolution already described; and the space between it and the upper surface of the corpus callosum is termed the callosal sulcus (sulci corporis callosi) (Figs. 562 and 567). The hemispheres should now be sliced off to a level with the upper surface of the corpus callosum,
when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the centrum ovale majus of Vieussens (Fig. 571).

The Corpus Callosum (Figs. 571, 574, and 586).—The corpus callosum is a thick stratum of transversely directed nerve-fibres, by which probably almost every part of one hemisphere is connected with the corresponding part of the other hemisphere (Figs. 572 and 573). It connects not only corresponding but also non-corresponding portions of the cortices. The fibres of this body, when they pass from it into the hemispheres radiate in various directions (radiatio corporis callosi) between the fibres of the corona radiata, to terminate in the gray matter of the periphery. According to Cajal the termination is in the layer of small pyramidal cells of the cortex. The corpus callosum thus connects the two hemispheres of the brain, forming their great transverse commissure, and at the same time roofs in the lateral ventricles (Fig. 575). The best conception of its size and form is obtained by making an anterior posterior vertical section through the centre of the brain (Figs. 574 and 586). It is then seen to be a long, thick, irregularly flattened arch, body of the corpus callosum (truncus corporis callosi); in front taking a sharp bend, the genu (genus corporis callosi) (Fig. 577), and dipping downward and backward to the base of the brain by a reflected portion, the beak or rostrum (rostrum corporis callosi), which is connected with the lamina cinerea; behind it terminates by a rounded end, which is folded over and is named the splenium (splenium corporis callosi) (Fig. 577). The corpus callosum is about four inches in length, and extends to within an inch and a half of the anterior and two inches and a half of the posterior extremity of the cerebrum. It is somewhat broader behind than in front, and is thicker at either end than in its central part. The reflected anterior portion of the corpus callosum is called the beak or rostrum; it becomes gradually thinner as it descends, and is attached by its lateral margins to the frontal lobes. At its termination, in addition to joining the lamina cinerea, the corpus callosum gives off on each side a band of white substance, the peduncle of the corpus callosum (gyrus subcallosus or pedunculus corporis callosi), already described (p. 882).

Posteriorly, the corpus callosum forms a thick rounded fold, called the pad or splenium, which is free for a little distance as it curves forward, and is then continuous by its under surface with the fornix. The splenium overlaps the mesencephalon, but is separated from it by the pia mater, which is prolonged forward to
form the velum interpositum (Fig. 548). On the upper surface of the corpus callosum the structure is very apparent, the fibres being collected into coarse transverse bundles (Fig. 571). Along the middle line is a longitudinal depression, the so-called raphé, bounded laterally on each side by two or more slightly elevated longitudinal bands (Fig. 571). The internal band on each side is called the stria longitudinalis medialis or nerve of Lancisi. The external band is the stria longitudinalis lateralis or taenia tectae. The external band is beneath the convolution of the corpus callosum. There is an attenuated sheet of gray matter with the external and internal striae, and it, with the striae, constitutes the so-called gyrus supra-callosus (pp. 882 and 886). On each side of the middle line the under surface of the corpus callosum forms the roof of the lateral ventricle, while in the mesial plane it is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms a vertical partition between the two ventricles (Figs. 574 and 586). On each side the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere cannot pass directly across, but have to take a curved direction. The part of the corpus callosum which curves forward on each side from the genu into the frontal lobe and covers the front part of the anterior cornu of the lateral ventricle is called the forceps anterior or forceps minor. The part which
curves backward from each side of the splenium into the occipital lobe is known as the **forceps posterior** or **forceps major**. Between these two parts on each side is a collection of fibres, which cover in the body of the lateral ventricle. These constitute the **tapetum** or **mat**. The tapetum helps to form the roof and outer wall of the posterior horn of the lateral ventricle and the outer wall of the posterior portion of the descending horn of the ventricle. These fibres were formerly regarded as fibres of the callosum, but in reality are the fibres of the **fasciculus occipito-frontalis** which diverge posteriorly. The corpus callosum contains a few projection fibres, but is chiefly composed of association fibres and branches from both association and projection fibres.

An incision should now be made through the corpus callosum, on either side of the raphé, when two large irregular cavities will be exposed, which extend through a great part of the length of each hemisphere. These are the lateral ventricles.

**The Lateral Ventricle** (**ventriculus lateralis**) (Fig. 575).—The lateral ventricle is an irregular cavity situated in the lower and inner parts of the cerebral hemisphere.

![Fig. 575.—The lateral ventricles of the brain.](image)

There are two lateral ventricles, one being placed on either side of the middle line. They are separated from each other by a mesial vertical partition, the **septum lucidum** (Figs. 574 and 586), but communicate with the third ventricle and indirectly with each other through the **foramen of Monro** (Figs. 548, 574, and 575). They are lined by a thin, diaphanous membrane, the **ependyma**, which is neuroglia covered by ciliated epithelium. The layer of neuroglia is absent over the optic thalamus and the choroid plexus. The lateral ventricles communicate with each other and with
the third ventricle, and are moistened by the cerebro-spinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a central cavity or body and three prolongations from it, termed cornua. The anterior cornu curves forward and outward into the frontal lobe; the posterior backward and inward into the occipital lobe; and the middle descends into the temporal lobe.

The Septum Lucidum (septum pellucidum) (Figs. 574, 586, and 587) is composed of two thin, vertical laminae, which lie in the median line with their mesial surfaces almost in contact. These sheets are triangular and can be separated, and the cavity thus shown is called the fifth ventricle (caurum septi pellucidum) (Fig. 575). It contains a little fluid, but does not communicate with the general ventricular cavity. Each lamina of the septum lucidum bears the name of the lamina septi pellucidi. The front part of the septum lucidum lies behind the genu of the corpus callosum, and below it passes toward the base of the brain between the fornix and the posterior margin of the rostrum, to terminate in the subcallosal gyrus. Posteriorly, the septum lucidum passes back between the fornix and the body of the corpus callosum, being attached to each structure.

The Central Cavity or Body of the lateral ventricle (ventriculus lateralis [pars centralis]) (Fig. 575) is situated in the lower part of the parietal lobe. It is an irregularly curved cavity, triangular in shape on transverse section, and presents a roof, a floor, an inner wall, and an outer wall. Its roof is formed by the under surface of the corpus callosum; its mesial wall is the septum lucidum, which separates it from the opposite ventricle and connects the under surface of the corpus callosum with the fornix; its external wall is the internal capsule; its floor is formed by the following parts, enumerated in their order of position, from before backward; the caudate nucleus of the corpus striatum, taenia semicircularis, the epithelial covered optic thalamus, the epithelial covered choroid plexus, the superior surface of the body of the fornix and part of its posterior pillar.

The Anterior Cornu or Frontal Horn (cornu anterius) (Fig. 575) passes forward and outward, with a slight inclination downward, from the foramen of Monro into the frontal lobe, curving round the anterior extremity of the caudate nucleus. Its roof is the forceps minor of the corpus callosum, and its floor the upper surface of the reflected portion of the corpus callosum, the rostrum. It is bounded mesially by the anterior portion of the septum lucidum, and externally by the head of the caudate nucleus of the corpus striatum. Its apex reaches the posterior surface of the genu of the corpus callosum.

The Foramen of Monro (foramen interventriculare) (Figs. 548, 574, 575, and 587) extends from the anterior and superior extremity of the third ventricle and the point of junction of the anterior horn with the central cavity of the lateral ventricle. It lies between the anterior pillar of the fornix and the anterior margin of the optic thalamus. This foramen connects the third ventricle with the two lateral ventricles.

The Posterior Cornu or Occipital Horn (cornu posterius) (Fig. 575) curves backward into the substance of the occipital lobe, its direction being backward and outward, and then inward; its concavity is therefore directed inward. Its roof is formed by the tapetum of the corpus callosum passing to the temporal and occipital lobes, which also helps to bound this horn externally. On its mesial wall is seen a longitudinal eminence, which is in an involution of the ventricular wall produced by the calcarine sulcus; this is called the hippocampus minor (calear avis). Just above this the forceps major of the splenium, sweeping around to enter the occipital lobe, causes another projection, which is known as the bulb of the posterior horn (bulbus cornu posterius). The hippocampus minor and bulb of the posterior horn are extremely variable in their degree of development, being in some cases ill defined, while in others they are unusually prominent. The balance of the posterior horn is bounded by the white substance of the occipital lobe.
Between the middle and posterior cornu is a triangular area, called the **trigonum ventriculi** (see Descending Horn).

The **Middle or Descending Cornu** or **Temporal Horn** (*cornu inferius*) (Figs. 575, 581, and 583), the largest of the three traverses the temporal lobe of the brain, forming in its course a remarkable curve around the back of the optic thalamus. It passes at first backward, outward, and downward, and then curves around the crus cerebri, forward and inward, to within an inch of the apex of the temporal lobe, its direction being fairly well indicated on the surface of the brain by that of the parallel sulcus. Its **antero-external boundary** or **roof** is formed by the under surface of the tapetum of the corpus callosum, the pulvinar of the optic thalamus, and the inferior layer of the internal capsule. The tail of the nucleus caudatus of the corpus striatum and the taenia semicircularis are also prolonged into it, and extend forward in the roof of the descending horn to its extremity, where they end in a mass of gray matter, the **amygdaloid nucleus** (*nucleus amygdalae*); this nucleus is merely a localized thickening of the adjacent gray cortex. The **posterior boundary** or **floor** of the **lateral ventricle** presents for examination the following parts: the **hippocampus major** (*hippocampus*), **pes hippocampi** (*digitationes hippocampi*), **eminentia collateralis** or **pes accessorius**, **corpus fimbriatum** (*fimbria hippocampi*), prolonged from the **posterior pillar of the fornix**, and the **choroid plexus**. Along the medial aspect of the descending cornu there is a cleft-like opening, the **choroid fissure**, which is the lower part of the transverse fissure, through which the choroid plexus of the pia mater is invaginated into the ventricle, but covered by the epithelium of the ependyma, which is pushed in before it. Upon the inner wall are also noted the **epithelial covering**, the **pulvinar**, and the **dentate convolution** or **fascia dentata hippocampi** (*fascia* *dentata hippocampi*) (Figs. 562 and 581), which is the irregular and free cortical margin.

The **Corpus Striatum** (Figs. 575, 576, 577, 580, and 584), the basal ganglion of the hemisphere, has received its name from the striped appearance which its section presents, in consequence of diverging white fibres being mixed with the gray matter which forms the greater part of its substance. It is situated to the front and to the outside of the optic thalamus. The corpus striatum measures about two inches in its antero-posterior diameter and one and a quarter inches transversely. The larger portion of this body is embedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the **extra-ventricular portion** or the **lenticular nucleus**

---

(nucleus lentiformis); a part, however, is visible in the ventricle and its anterior cornu; this is the intra-ventricular portion or the caudate nucleus (nucleus caudatus). These two portions are separated by the internal capsule.

The caudate nucleus (nucleus caudatus) (Figs. 576, 577, 579, and 580) is a pear-shaped, highly arched mass of gray matter; its broad anterior extremity, the bulb or head (caput nuclei caudati), is directed forward into the forepart of the body and anterior cornu of the lateral ventricle; its narrow posterior end, the tail or surcingle (cauda nuclei caudati), is directed outward and backward on the floor of the body of the lateral ventricle and on the outer side of the optic thalamus, from which structure it is separated by the taenia semicircularis (Fig. 577); it is continued downward into the descending cornu of the lateral ventricle and is continued forward in the roof to terminate in the amygdaloid nucleus, a collection of gray matter in the apex of the temporal lobe. It is covered by the lining of the ventricle, and crossed by some veins of considerable size. It is separated from the extra-ventricular portion, in the greater part of its extent, by a lamina of white matter which is called the internal capsule, but the two portions of the corpus striatum are united in front.

The lenticular nucleus (nucleus lentiformis) (Figs. 576, 577, 579, and 580) is a mass of gray matter which lies external to the caudate nucleus and the thalamus, and is only seen in sections of the hemisphere. The laminae of the internal capsule separate it from the ventricle. If a coronal section is made through the anterior portion of the lenticular nucleus, it is seen to be continuous below with the head of the caudate nucleus (Fig. 578). Above strands of gray matter join the two nuclei,
and these bands pass through the anterior part of the white internal capsule and give it a striated appearance; hence the term corpus striatum, which is applied to the mass of which the two nuclei are parts. When divided horizontally, it presents, to some extent, the appearance of a biconvex lens, while a vertical transverse section of it gives a somewhat triangular outline. It does not extend as far forward or backward as the nucleus caudatus. It is bounded externally by a lamina of white matter called the external capsule (capsula externa) (Figs. 576, 577, 578, and 579), on the outer surface of which is a thin layer of gray matter termed the bulwark or claustrum (Figs. 576, 577, 578, and 579). The claustrum presents ridges and furrows on its outer surface, corresponding to the convolutions and sulci of the island of Reil, from which it is separated by a thin white lamina (Figs. 576, 577, and 578).

Upon making a transverse vertical section through the middle of the lenticular nucleus, it is seen to present two white lines, external and internal medullary laminae (laminae medullare externa et interna) (Fig. 579), parallel with its lateral border, which divide it into three zones, of which the outer and largest is of a reddish color, and is known as the putamen, while the two inner are paler and of a yellowish tint, and constitute the globus pallidus (Figs. 578 and 579). All three zones are marked by fine radiating white fibres, which are most distinct in the putamen. The gray matter of the corpus striatum is traversed by nerve-fibres, some of which are believed to originate in it. The cells of the corpus striatum are multipolar, both large and small; those of the lenticular nucleus containing yellow pigment.

The internal capsule (capsula interna) (Figs. 576, 577, 578, 579, and 580) is formed by fibres of the crus of the crus cerebri, supplemented by fibres derived from the corpus striatum and optic thalamus on each side. Sagittal section exhibits a superior lamina and an inferior lamina, continuous with each other behind, but separated in front by the Sylvian fissure. The inferior lamina is thin and its fibres terminate in the parietal and temporal lobes. The superior lamina is thick, contains most of the crus, and the term internal capsule as usually employed is synonymous with it. In horizontal section (Figs. 576, 577, 578, and 579) the internal capsule is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the knee or genu of the internal capsule (genu capsule internal) (Fig. 578), and projects between the caudate nucleus and the optic thalamus. The portion in front of the genu is termed the frontal portion, the anterior limb or the lenticulo-striate division (pars frontalis capsule internae), and separates the lenticular from the caudate nucleus; the portion behind the genu is the occipital portion, the posterior limb or the lenticulo-optic division (pars occipitalis capsule internae), and separates the lenticular nucleus from the optic thalamus.

Fibres of the Internal Capsule (Figs. 578 and 579). Inferior Lamina.—The fibres of the inferior lamina of the internal capsule pass externally under the lenticular nucleus, over the amygdala and descending horn of the lateral ventricle, and reach the parietal lobe and the temporal lobe. The motor fibres constitute a portion of the motor tempo-ro-pontal tract which extend from the temporal cortex to the nucleus pontis. The sensory fibres consist of a portion of the acoustic radiation, which passes from the corpus geniculata interna to the auditory cortex in the temporal lobe, and ansa peduncularis, a tract of common sensation which passes from the optic thalamus to the sensory region of the cortex. Some of the fibres of the median fillet join the ansa peduncularis and pass through the inferior lamina.

Superior Lamina.—This portion is often spoken of as though it were the entire internal capsule. It contains the greater part of the crusa and enters the corona radiata. The pyramidal tract is in the knee of the internal capsule. Its fibres come from the cortical region about the central sulcus of Rolando and
pass through the knee of the internal capsule; most of them, by way of the middle of the crusata, to reach the spinal cord (p. 907); some of them end in the pons and medulla. The anterior segment of the superior lamina of the internal capsule contains motor fibres which come from the prefrontal region of the cortex and pass by way of the inner one-fifth of the crusata to the nucleus pontis and nuclei of cranial nerves. These fibres constitute the **fronto-pontal tract** (tractus cerebrocorticofrontalis pontalis). In the posterior segment of the superior lamina of the internal capsule is a part of the tract from the temporal cortex to the nucleus pontis and the nuclei of cranial motor nerves, the balance

(M. Allen Starr, after von Monakow.)
of which tract is in the inferior lamina. This path occupies the outer one-fifth of the crista, and is the temporo-pontal tract (tractus cerebrocorticopontalis temporalis).

The sensory fibres include common sensory fibres and fibres of special sense. Fibres of common sensation exist in both the anterior and posterior segments, and these fibres pass from the optic thalamus to the sensory region of the cortex, and are known as the cortical fillet. The fibres of special sense are found where the superior lamina joins the inferior lamina.

The optic radiations of Gratiolet (radiatio oecipitothalamica [Gratioleti]) are in the portion back of the lenticular nucleus, and pass from the optic thalamus and corpus geniculatum externum to the cuneus.

The auditory radiations (radiatio temporothalamica) are also back of the lenticular nucleus and pass from the corpus geniculatum externum to the temporal cortex.

Numerous fibres of the internal capsule give off collaterals which reach the opposite hemisphere by way of the corpus callosum, none of them reaching the cortex.

Note.—The above description of the fibres of the internal capsule is largely taken from the Anatomy of the Brain and Cord, by Harris E. Santee, M.D.

As the fibres of the internal capsule ascend to reach the various convolutions of the cerebral hemisphere they spread out like an open fan. This expansion is the corona radiata. The constituent parts and fibre-groups of the internal capsule are shown in Figs. 578 and 579.

The external capsule (capsula externa) (Figs. 576, 577, 578 and 579) is a lamina of white matter, situated on the outer side of the lenticular nucleus, between it and the claustrum, and is continuous with the internal capsule in front of and behind the putamen. It is made up of fibres derived partly from the anterior white commissure (Fig. 580) and partly from the subthalamic region.

The Claustrum (Figs. 576, 577, 578, and 579) is a thin layer of gray matter, situated on the outer surface of the external capsule. On transverse section it is seen to be triangular, with its apex directed upward and its base downward. Its inner surface, which is contiguous to the external capsule, is smooth, but its outer surface presents ridges and furrows which correspond with the convolutions and sulci of the island of Reil, with which it is in close relationship. The claustrum is regarded as a detached portion of the gray matter of the island of Reil, from which it is separated by a layer of white fibres, the band of Baillarger (capsula extrema) (Figs. 576 and 577). The cells of the claustrum are small and spindle-shaped, and contain yellow pigment; they are similar to those found in the deepest layer of the cortex.

The Taenia Semicircularis (stria terminalis) (Figs. 575, 577, and 584) is a narrow, whitish band of medullary substance, situated in the depression between the caudate nucleus and the optic thalamus. Anteriorly its fibres are partly continued into the anterior pillar of the fornix; some, however, pass over the anterior commissure to the gray matter between the caudate nucleus and septum lucidum, while
others penetrate the caudate nucleus. Posteriorly it is continued into the roof of the middle or descending horn of the lateral ventricle, at the extremity of which it enters the amygdaloid nucleus, an oval mass of gray matter, situated in the roof of the lower extremity of the descending horn. Like the corpus striatum, it is formed by a localized thickening of the gray matter of the cortex cerebri. Superficial to it is a large vein, *vena corporis striati*, which receives numerous small veins from the surface of the corpus striatum and optic thalamus; it unites with the choroid vein to form the vein of Galen (p. 556). On the surface of the vein of the corpus striatum is a narrow band of white fibres, named the *lamina cornea*.

The remains of the corpus callosum should now be removed in order to expose the fornix.

The Fornix (Figs. 574, 575, 576, 577, 580, 582, 583, 586, and 587).—The fornix is a longitudinal, arch-shaped lamella of white matter, situated beneath the corpus callosum, with which it is continuous behind, but from which it is separated in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for either hemisphere. The two portions are not united to each other in front and behind, but their central parts are joined together in the middle line. The two anterior, separated parts are called the *anterior pillars*; the intermediate united portions constitute the *body of the fornix*; and the posterior parts, which are also separated from each other, are called the *posterior pillars*.

The *Body of the Fornix* (*corpus fornicis*) is triangular, narrow in front, broad behind. Its *upper surface* is connected, in the median line, to the septum lucidum in front, and the corpus callosum behind; laterally this surface forms part of the floor of each lateral ventricle. Its *under surface* rests upon the velum interpositum, which separates it from the third ventricle and the inner portion of the upper surface of the optic thalami. Its outer edge, on each side, is free, and is connected with the choroidalplexuses.

The *Anterior Pillars of the Fornix* (*columnae fornicis*) arch downward toward the base of the brain and are separated from each other by a narrow interval. They are composed of white fibres, which descend immediately behind the anterior commissure, where each anterior pillar passes through the inner part of the optic thalamus of that side. At the base of the brain each pillar becomes twisted upon itself to form a loop, somewhat resembling the figure 8. The lowest part of the loop constitutes the white matter of the corresponding *corpus albinus*, from which the fibres can apparently be traced upward and backward, as the bundle of *Vicq d'Azyr*, into the substance of the corresponding optic thalamus (Figs. 574 and 586). It must be stated, however, that there is probably no direct continuity between this bundle and the anterior pillar of the fornix—the latter possibly ending in the gray matter of the corpus albinus. The anterior pillars of the fornix are joined in their course by the *peduncles of the pineal gland* and the superficial fibres of the *taenia semicircularis*, and receive fibres from the septum lucidum. Zucker-kandl describes an *olfactory fasciculus*, which becomes detached from the main portion of the anterior pillar of the fornix, and passes downward, in front of the anterior commissure, to the base of the brain, where it divides into two bundles, one joining the inner root of the olfactory tract; the other, the peduncle of the corpus callosum, and through it reaching the hippocampal convolution.

Between the anterior pillars of the fornix and the anterior extremity of the optic thalamus an oval aperture is seen on each side; this is the *foramen of Monro* (*foramen interventriculare*) (Figs. 548, 574, 575, and 587). The two openings descend toward the middle line, and lead into the upper part of the third ventricle. Through this foramen the lateral ventricles communicate with the third ventricle, and consequently with each other; through it also the two choroidalplexuses become joined with each other across the middle line. The boundaries of the
opening are, above and in front, the anterior pillars of the fornix; behind, the anterior extremity of the optic thalamus.

The **Posterior Pillars of the Fornix** (crura fornixis) are the backward prolongations of the two halves of the body of the fornix. They are flattened bands, and, at their commencement, are intimately connected by their upper surfaces with the corpus callosum. Diverging from one another, each curves round the posterior extremity of the optic thalamus, and then passes downward and forward into the descending horn of the lateral ventricle. Here it lies along the concavity of the hippocampus major, on the surface of which some of its fibres are spread out, the alveus, while the remainder are continued, as the fimbria, the corpus fimbriatum, the taenia fornixis or the taenia hippocampi (for it bears these different names) (Figs. 562, 575, 577, and 583), into the hook or uncus of the hippocampal convolution. Upon examining the under surface of the fornix, between its diverging posterior pillars, a triangular portion of the under surface of the corpus callosum may be seen. On it are a number of curved or oblique lines passing between the two pillars of the fornix. This portion has been termed the lyra or psalterium (Fig. 583), from the fancied resemblance it bears to a harp. It is also called the commissura hippocampi. In some cases there is a small space intervening between the lyra and the under surface of the corpus callosum known as Verga's ventricle.

The **Anterior Commissure of the Cerebrum** (commissura anterior cerebri) (Figs. 580, 584, and 587).—The anterior commissure of the cerebrum is a bundle of white fibres, in the anterior wall of the third ventricle, placed in front of the anterior pillars of the fornix, behind the rostrum of the corpus callosum, and resting upon the lamina terminalis. The anterior commissure connects the two hemispheres, and in vertebrates possessing a corpus callosum is an extremely important structure. On transverse section it is oval in shape, its largest diameter being vertical in direction and measuring about one-fifth of an inch. Its fibres pass backward and downward through the globus pallidus and below the putamen on each side, from which point most of the fibres radiate to the cortex, but some go to the external capsule. The fibres of the anterior commissure are divisible into two groups: 1. An anterior group (pars anterior or pars olfactoria), the fibres of which join the limbic lobes and connect each limbic lobe to the olfactory tract of the opposite side. The fact that the pars anterior contains fibres from the olfactory tract of the opposite side may serve to explain the condition of crossed anosmia, e. g., where there is a lesion in one temporal lobe with a loss of smell in the olfactory area of the opposite side of the nose. 2. A posterior group (pars posterior or pars occipitotemporalis), the fibres of which pass to the cortex of the temporal lobe and of the lower part of the occipital lobe.

The **Septum Lucidum** (septum pellucidum) (Figs. 574, 586, and 587).—The septum lucidum is a thin, double, vertically placed partition, which forms the internal boundary of the body and anterior horn of the lateral ventricle. It consists of two distinct laminae, separated in part of their extent by a narrow chink or interval,
THE HEMISPHERES OF THE CEREBRUM

called the **fifth ventricle.** It is a thin, semitransparent septum, attached, above, to the under surface of the corpus callosum; in front to the reflected portion of the corpus callosum; below it passes between the fornix and the posterior margin of the rostrum to terminate in the sub-callosal gyrus; posteriorly it is between the fornix and body of the corpus callosum, being attached to each. It is triangular in form, broad in front and narrow behind; its inferior angle corresponds with the upper part of the anterior commissure. The outer surface of each lamina is directed toward the lateral ventricle, and is covered by the ependyma of that cavity, while its medial surface bounds the cavity of the fifth ventricle (p. 889).

**Fifth Ventricle (ca* *vum se* *pti pellucidi).**—The fifth ventricle was originally a part of the great longitudinal fissure, which was shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum is therefore formed by the medial wall of the hemisphere, and consists of an internal layer of gray matter, derived from the gray matter of the cortex, and an external layer of white substance continuous with the white matter of the cerebral hemispheres. The fifth ventricle differs from the other ventricles of the brain, inasmuch as it is not developed from the cavity of the cere-

![Fig. 581. Transverse section of the middle horn of the lateral ventricle. (From a drawing by Mr. F. A. Barton.]

bral vesicles, it is not lined by ciliated epithelium but by altered pia mater, and it does not communicate with the general ventricular cavity; further, the fluid it contains is not cerebro-spinal fluid but is of the nature of lymph.

The structures on the floor of the descending horn of the lateral ventricle will now be described.

The **Hippocampus Major or Cornu Ammonis** (Figs. 581 and 583) is a white eminence, about two inches in length, of a curved elongated form, extending throughout the entire length of the floor of the descending horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presenting two or three rounded elevations with intervening depressions, it resembles the paw of an animal, and is called the **pes hippocampi** (*digitationes hippocampi*) (Fig. 583). If a transverse section is made through the hippocampus major, it will be seen that this eminence is produced by the folding of the cortex of the brain to form the **dentate or hippocampal sulcus** (Figs. 562, 563, 564, and 567). The dentate fissure is separated from the choroid fissure by the **dentate gyrus** or **dentate fascia** (*fascia dentata*) (Figs. 562 and 581). The hippocampal gyrus and the fifth temporal gyrus together constitute the **uncinate convolution** (Figs. 567 and 581). The **uncus** (Fig. 581) is the
hook-like anterior extremity of the hippocampal or uncinate gyrus. To the outer side and parallel with the hippocampus major an elongated eminence, the \textit{eminentia collateralis}, is frequently recognized (Fig. 581). It corresponds with the middle part of the collateral fissure, and its size depends on the direction and depth of this fissure. The main mass of the hippocampus major consists of gray matter, but on its ventricular surface is a thin layer of white matter, known as the \textit{alveus}, which is continuous with the corpus fimbriatum of the fornix and is covered by the ependyma of the ventricle. Dr. J. G. Macarthy, of McGill University, Montreal, has shown\textsuperscript{1} that, if the alveus and superficial strata of gray matter be reflected from the surface of the hippocampus by an incision carried along its convexity, the "core" of the hippocampus, as he terms it, presents in many cases a corrugated or crimped appearance.

The \textbf{Corpus Fimbriatum}, \textbf{Taenia Fornicis}, or \textbf{Fimbria} (\textit{taenia hippocampi} or \textit{taenia fimbriae}) (Figs. 562, 575, 577, and 583) has already been mentioned as a part of the posterior pillar of the fornix. It consists of a narrow white band, which is placed immediately below the choroid plexus, and is attached by its deep surface to the

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{f582.png}
\caption{Diagram showing the mode of formation of the velum interpositum.}
\end{figure}

white matter or \textit{alveus} of the hippocampus major as it courses through the descending cornu of the lateral ventricle. It can be traced as far as the uncus or hook of the hippocampal gyrus. Its inner margin is free, and rests upon the dentate fascia, from which it is separated by a slit-like fissure, the \textit{fimbrio-dentate fissure}. The groove between the fimbria and the hippocampal convolution is the defile of the dentate fissure. Its outer margin is attenuated and irregular, and forms the line along which the ependyma is reflected over the choroid plexus as the latter is invaginated through the inferior part of the transverse fissure. When the choroid plexus is pulled away it carries the ependyma with it, and the descending horn opens on to the surface of the brain through the transverse fissure. If now the inner border of the corpus fimbriatum be raised, a notched band of gray matter, which is a free border of cortex, and is called the \textit{dentate fascia} (\textit{fascia dentata hippocampi}) (Figs. 562 and 581), will be exposed; this has already been described as forming part of the limbic lobe (p. 879).

\textsuperscript{1} Journal of Anat. and Phys., 1899, vol. xxiii.
The Choroid Plexus (plexus chorioideus) (Figs. 548, 575, and 583) is a highly vascular, fringe-like structure, which is situated partly in the body and partly in the descending cornu of the lateral ventricle. It will be desirable to consider these two portions separately, in order to get a just conception of how they are formed.

The portion in the body of the ventricle is the vascular, fringed border of a triangular fold of pia mater, the velum interpositum (tela chorioidea superior or tela chorioidea ventriculi tertii), which lies on the under surface of the fornix and forms the roof of the third ventricle. The developing brain vesicles are covered by pia mater. As the prolongation from the first vesicle, which is to form the cerebral hemispheres, increases in size, it grows backward and downward and covers the other vesicles, with the result that the pia mater covering the hemisphere comes in contact with that covering the upper surface of the second vesicle. Portions of the two layers which are in contact form the velum interpositum. Immediately above is the body of the fornix, which is formed by the fusion of the cerebral hemispheres in the middle line, and below is the cavity of the second vesicle (the third ventricle), with the optic thalamus on either side. Just beyond the free lateral border of the fornix, between it and the taenia semicircularis, is a portion of the first cerebral vesicle, which is not developed into nervous matter, but is made up only of ependyma covered by pia mater. The vessels of this portion of the highly vascular pia mater become dilated and prolonged, and grow into the ventricle, pushing the
ependyma before them, and forming an irregular congeries of vessels, apparently encroaching on the cavity of the lateral ventricle, but in reality being external to it, because they are separated from it by the lining membrane of the cavity, the ependyma. This vascular structure is the choroid plexus of the body of the ventricle.

The part of the choroid plexus seen in the descending cornu is formed in exactly the same way—viz., by an ingrowth of the vessels of the pia mater into the cavity, pushing the ependyma before it, at a part of the wall of the horn where there is a similar absence of nervous tissue and where it consists simply of pia mater and ependyma in close contact. This portion lies between the corpus fimbriatum in the floor and the taenia semicircularis in the roof of the descending horn. This area, destitute of nervous matter, is continuous with the area in the body of the ventricle, from which the choroid plexus of this region originated, and in it the vessels of its pia mater increase, and, invaginating the ependyma, appear in the descending horn as its choroid plexus. In the body of the ventricle the choroid plexus is really the vascular fringed margin of the velum; beyond the posterior margin of the velum the plexus of the descending horn is continuous with the pia mater on the surface of the gyrus hippocampi; the two portions of the plexus are, however, directly continuous with each other, and constitute the choroid plexus of the lateral ventricle (plexus choroideus ventriculi lateralis). The gap or cleft through which the invagination of the pia mater takes place is called the choroid fissure.

In front the choroid plexus of the lateral ventricle is small and tapering, and communicates with the plexus of the opposite side through the foramen of Monro. In structure it consists of minute and highly vascular villous processes, containing an afferent and efferent vessel, and covered by a single layer of flattened epithelium, the cells of which often contain yellowish fat molecules. The anterior choroidal artery is derived from the internal carotid, and enters the ventricle at the extremity of the descending cornu, and, after ramifying in the plexus, sends branches into the adjacent parts of the brain. The posterior choroidal arteries, one or two in number on each side, are derived from the posterior cerebral artery, and reach the plexus by passing forward under the splenium of the corpus callosum. The veins of the choroid plexus unite to form a prominent vein, the choroid vein, which courses from behind forward to the foramen of Monro. On each side of the foramen of Monro a deep cerebral vein or vein of Galen is formed by the union of the choroid vein and the vein of the corpus striatum. The veins of Galen pass back in the velum interpositum, unite to form the common vein of Galen or the vena magna Galeni (v. cerebri magna), which empties into the straight sinus (p. 735).

The Transverse Fissure or Fissure of Bichat (fissura cerebri transversa), separates the cerebrum from the cerebellum. This fissure passes forward and ends in the cerebrum as the lateral part of the transverse fissure or the choroid fissure (fissura chorioidea). The posterior part of the transverse fissure is occupied by the tentorium. Posteriorly the transverse fissure has above it the mass of the cerebral-hemisphere and below it the upper surface of the cerebellum, the corpora quadrigemina, and the pineal gland. The transverse fissure is a complete fissure, but it is filled by the invagination of the pia mater, forming laterally the velum interpositum and the choroid plexuses, which invagination is covered by the lining of the ventricular cavities. If this involution of pia mater is pulled out, the ventricular lining will necessarily be torn away with it, and a cleft-like space will be left on either side, extending from the foramen of Monro to the bottom of the descending horn of the lateral ventricle. The upper part of the cleft, that is to say, the part nearest the foramen of Monro, is between the lateral border of the body of the fornix and the optic thalamus; below this, at the commencement of the middle horn, it is between the commencing corpus fimbriatum
of the fornix and the pulvinar of the optic thalamus; and lower still, in the descending horn, between the corpus fimbriatum on the floor and the taenia semicircularis in the roof of the cornu. The course of the choroid fissure from the foramen of Monro is backward, downward, and forward, to near the apex of the temporal lobe. The choroid fissures of the two sides are continuous between the fornix and the roof of the third ventricle.

The Velum Interpositum or Tela Chorioidea Superior (tela chorioidea ventriculi tertii) (Fig. 548) is a vascular membrane, and is a prolongation of the pia mater into the interior of the brain through the middle part of the transverse fissure. It is of a triangular form, and separates the under surface of the body and posterior pillars of the fornix from the cavity of the third ventricle. Laterally it covers the inner part of the upper surface of the optic thalamus. Its posterior border or base lies beneath the splenium of the corpus callosum above, and the optic thalamus, the corpora quadrigemina, and pineal body below. The upper layer of the base is continuous with the pia mater of the occipital lobe, and the lower layer of the base is continuous with the pia mater of the dorsal aspect of the cerebellum and mid-brain. Its anterior extremity or apex ends just behind the anterior commissure, where it receives the anterior extremities of the choroid plexuses, which are here united through the foramen of Monro, and are then prolonged backward on the under surface of the velum as the choroid plexus of the third ventricle (plexus chorioideus ventriculi tertii). The inferior layer of the velum which carries the choroid plexus of the third ventricle is called the superior choroid tela (tela chorioidea ventriculi tertii). The external portion of the inferior layer of the velum interpositum covers the inner half of the superior surface of the optic thalamus. In front the plexuses of the third ventricle lie close to the middle line, but diverge from each other behind. Each lateral margin of the velum interpositum constitutes the choroid plexus of the corresponding lateral ventricle. It is supplied by the anterior and posterior choroidal arteries, already described. The veins of the velum interpositum, the venae Galeni (vv. cerebri internae), two in number, run between its layers, each being formed by the union of the vein of the corpus striatum (v. corporis striata) with the choroid vein (v. chorioidea). The venae Galeni unite posteriorly into a single trunk, the venae magna Galeni or the common vein of Galen (v. cerebri magna), which terminates in the straight sinus (Fig. 548). The portion of the pia mater prolonged over the lower half of the fourth ventricle is known as the tela chorioidea inferior quarti. It carries the choroid plexus of the fourth ventricle (plexus chorioideus ventriculi quarti.)

II. The Inter-brain (Thalamencephalon).

The inter-brain is the region of the third ventricle, and comprises the parts developed from the second cerebral vesicle, together with parts from that portion of the first vesicle which is not concerned in the formation of the cerebral hemispheres. The inter-brain is connected above and in front with the cerebral hemispheres; behind, with the mid-brain or mesencephalon. On its upper surface it is entirely concealed from view, as it is covered by those portions of the internal surfaces of the cerebral hemispheres which have fused together to form the corpus callosum and the fornix, and is separated from the latter by the two layers of pia mater which form the velum interpositum. Inferiorly it reaches the base of the brain, forming the structures contained in the interpeduncular space.

The Third Ventricle (ventriculus tertius) (Fig. 584).—The third ventricle is the cavity of the inter-brain; it is in the mid-line, is at a lower level than the lateral ventricles; and the epithelial layer of the ependyma from the lateral ventricles is prolonged into the third ventricle through the foramen of Monro. The third ven-
The third ventricle contains cerebro-spinal fluid. It is a narrow median crevice between the two optic thalami, which constitute the side walls of the inter-brain. It is "about an inch in length from before backward and one-quarter of an inch broad at its widest part." Its roof is formed by the velum interpositum, from which is suspended the choroid plexus of the third ventricle. Its floor, somewhat oblique in its direction, is formed, from before backward, by the tuber cinereum, with its infundibulum and pituitary body; the corpora albicantia; the posterior perforated space; and the tegmenta of the crura cerebri. Its sides are formed by the optic thalami, and are limited above by a delicate band of white fibres, the pineal stria (stria medullaris thalami), which runs along the junction of the mesial and upper surfaces of the optic thalamus to join the anterior pillars of the fornix. Its sides are somewhat convex, so that in the middle of the ventricle the two lateral walls are almost in contact, and are here united across the middle line by a band of gray nervous matter, the middle, gray, or soft commissure (Fig. 584). The ventricle is bounded in front by the anterior pillars of the fornix and the lamina cinerea; behind by the pineal gland, the posterior commissure, and the upper end of the aqueduct of Sylvius, the iter a tertio ad quartum ventriculum. The cavity is much deeper in front than behind, and presents a recess at its anterior part, which lies over the optic commissure and is, therefore, termed the optic recess (recessus opticus). Behind and below this is the conical depression of the infundibulum (Fig. 587), passing

---

Fig. 584.—The third and fourth ventricles. An arrow has been placed in the position of the foramen of Monro.

1 Anatomy of the Brain and Spinal Cord. By Harris E. Santee.
downward and forward to the pituitary body. At its posterior extremity the cavity forms another and smaller recess, which extends into the stalk of the pineal gland, and is termed the pineal recess (recessus pinealis). The anterior part of the third ventricle is called the aula. At the upper and anterior part of the third ventricle, immediately behind the anterior pillars of the fornix and in front of the optic thalamus, is an opening, the foramen of Monro (foramen interventriculare [Monroi]), by which this ventricle communicates with the lateral ventricle on either side (Figs. 548, 574, 575, and 587). The foramen of Monro opens into each lateral ventricle at the point of junction of the anterior horn and the body of the ventricle. It lies between the anterior pillar of the fornix and the anterior margin of the optic thalamus and ends by opening into the anterior and superior extremity of the third ventricle. Running back from the foramen of Monro toward the aqueduct of Sylvius is a furrow called the sulcus of Monro (sulcus hypothalamicus [Monroi]). At the posterior part of the floor of the third ventricle, beneath the posterior commissure, is the opening of the aqueduct of Sylvius or iter a tertio ad quartum ventriculum (Fig. 587), the channel which joins the third and fourth ventricles (p. 912). The roof of the cavity of the third ventricle is limited in front and behind by transverse bands of white matter, known respectively as the anterior and posterior commissures. The former has already been described in connection with the corpus striatum (p. 896).

The Middle, Gray, or Soft Commissure (massa intermedia or commissura mollis) (Fig. 584).—The middle, gray, or soft commissure consists almost entirely of gray matter. It connects the two optic thalami, and is continuous with the gray matter lining the anterior part of the third ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting; it is sometimes double.

The Posterior Commissure (commissura posterior) (Figs. 584 and 587).—The posterior commissure is a rounded band of white fibres, which stretches across from one optic thalamus to the other, overlying the upper end of the aqueduct of Sylvius. It is usually described as belonging to the inter-brain, but would appear to belong in part to the mid-brain, since some of its fibres are commissural and connect the anterior corpora quadrigemina to the fillet of the opposite side (see below). In addition there are other decussating fibres, which come from the tegmentum of the crus cerebri on one side and decussate with those of the opposite side in the posterior commissure, and passing through the optic thalamus reach the cerebral hemispheres. Fibres have also been described as taking their origin in the pineal body and ganglion habenulae, and passing across to the posterior longitudinal bundle and oculomotor nucleus of the opposite side; these fibres occupy the ventral part of the commissure, and receive their myelin sheath before those in its dorsal part. But to a certain extent the posterior commissure belongs to the inter-brain, since it contains fibres which serve as commissural fibres between the two optic thalami.

The Optic Thalamus (thalamus) (Figs. 576, 577, 578, 579, 580, 582, and 584).—The optic thalami are two large oblong masses, situated on either side of the third ventricle, and lying between the diverging portions of the corpora striata. They are composed mainly of gray matter, but the free surface of each is coated with a thin layer of white nervous tissue, the stratum zonale. They present outer and under surfaces, which are not free, but are blended with contiguous parts of the brain, and upper, inner, and posterior surfaces, which are free. The anterior extremity is narrow, and forms the posterior boundary of the foramen of Monro. The outer surface is in contact with the posterior limb of the internal capsule, which separates it from the lenticular nucleus. The inferior surface rests upon and is continuous with the tegmentum of the crus cerebri. Its upper surface is free, and is separated from the caudate nucleus by a furrow which lodges the vein of the
corpus striatum, and the taenia semicircularis. It is divided into an outer and an inner part by a groove which runs from behind, forward, and inward. The outer part forms a portion of the floor of the lateral ventricle, and is covered by the ependyma of that cavity; it terminates in front in a tubercle, the anterior tubercle of the optic thalamus (tuberculum anterius thalami). The inner part is covered by the velum interpositum, which separates it from the fornix, and is excluded from both the lateral and third ventricles by the reflection of the lining of these cavities, and is therefore destitute of an ependymal covering.

The internal surface forms the lateral wall of the third ventricle, and running along its upper border is the peduncle of the pineal gland, from which the ependyma of the third ventricle is reflected on to the under surface of the velum interpositum. The shelf-like edge of the ependyma separates the superior from the internal surface of the thalamus. The edge is called the taenia thalami, and close to it is a narrow band of longitudinal fibres called the pineal striae (striae medullaris thalami). The taenia thalami and the pineal striae pass backward and then inward into the stalk of the pineal gland. The portion of the taenia which turns inward has posterior to it a small triangular depression called the trigone of the habenula (trigonum habenulae). This depression is just in front of the superior quadrigeminal body. Passing in a medial direction from the trigonum habenulae is a collection of white fibres, the habenula. The fibres of the anterior portion of this band are continuous with those of the opposite side, and constitute the commissure of the habenula (commissura habenularum). The fibres of the posterior portion constitute the peduncle of the pineal gland (p. 906). The posterior surface projects beyond the level of the corpora quadrigemina, and forms a well-marked rounded prominence, the posterior tubercle or pulvinar. The pulvinar is continued externally into a second eminence, the external geniculate body (corpus geniculatum laterale), which is placed above and to the outer side of the internal geniculate body (corpus geniculatum mediale), and from which it is separated by the superior brachium, one of the roots of the optic tract.

The optic or free upper surface of the thalamus is covered by white fibres derived, in part, at least, from the optic tract and radiation. The thalamus is formed chiefly of gray matter, which is arranged in three masses partially separated from each other by white matter called the internal medullary lamina (lamina medullaris interna), which is named internal in contradistinction to a second or external medullary lamina (lamina medullaris externa), which coats the outer surface of the thalamus and lies between it and the internal capsule. These masses of gray matter are the nuclei of the optic thalamus. Twenty nuclei have been described (Nissl). The chief nuclei are the following:

1. The External or Lateral Nucleus (nucleus lateralis thalami).—The external or lateral nucleus, the largest of the nuclei, between the external and internal medullary laminae and extending the entire length of the thalamus, including, as Prof. Cunningham points out, the entire pulvinar, most of the segmental fibres, and one-fifth of the optic fibres, terminate in this nucleus, and from it originate the fibres of the thalamic radiation.

2. The Middle or Internal Nucleus (nucleus medialis thalami).—The middle or internal nucleus is separated by the internal medullary lamina from the other gray nuclei of the same side. It joins the middle nucleus of the opposite thalamus by means of the middle commissure.

3. The Anterior Nucleus (nucleus anterior thalami).—The anterior nucleus is in the anterior tubercle, and in it terminate the fibres of the bundle of Vicq d'Azyr which come from the corpus mamillare (Fig. 586).

In the substance of the thalamus are two other distinct nuclei, (4) the central nucleus of Luys and (5) the nucleus arcuatus. The nucleus or ganglion of the habenula lies in the trigonum habenulae.
Connections of the Optic Thalamus (Figs. 586, 589, and 590).—The optic thalamus is a ganglion interposed between the sensory tracts in the tegmentum and the cerebral cortex, being connected also with the optic tract. In this ganglion or in the adjacent ganglia of the subthalamic region, “almost every impulse of general sensation, on its journey to the cerebral cortex, is transferred to a higher neurone.” The crus of the crus cerebri is external to the optic thalamus and passes into the internal capsule. The tegmental fibres of the crus (Fig. 586) pass to the under surface of the thalamus, and the forward prolongation of the tegmentum which becomes continuous with the under surface of the thalamus is called the subthalamic region, and most of the longitudinal fibres enter this ganglion, some of them terminating in it, some of them traversing it and entering the internal capsule. The internal capsule (Figs. 578, 589, and 590) is composed of fibres going to and coming from the cerebral cortex. Most of these fibres are descending and form the crus cerebri. From all over the external surface of the optic thalamus fibres emerge, pass into the internal capsule, and from there go to the cerebral cortex. These fibres constitute the thalamic radiation.

The nuclei of the thalamus have been described (p. 904). The white matter receives the fibres of the tegmentum and fillet, the majority of which enter the lateral nucleus; it receives fibres (axones) from the entire cerebral cortex and sends fibres to the cortical special sense areas of sight, hearing, and smell and to the area of general sensation) the somaesthetic area).

The following groups of fibres of white matter are found in the thalami: 1. The anterior pillar of the fornix, which passes through the inner part of the optic thalamus on its way to the corpus mamillare, and the bundle of Vicq d’Azyr, (fasciculus thalamomamillaris) (Fig. 558), which arises in the corpus mamillare and ascends to the anterior gray nucleus. 2. Two bundles of fibres emerging from the external surface of the thalamus. The superior bundle (ansa lenticularis) arises largely in the lateral nucleus, passes through the internal capsule and the lenticular nucleus; it then enters the external capsule, and passes to the insula, the para-central lobule, the superior frontal convolution, and “the entire limbic lobe” (Fig. 589). The inferior bundle (ansa peduncularis) arises in the lateral nucleus, passes through the internal capsule below the lenticular nucleus, “enters into both the medullary laminae of that nucleus and the external capsule. It ends chiefly in the cortex of the ascending frontal and ascending parietal convolutions” (Fig. 589). These fibres constitute the ventral or inferior stalk of the thalamic radiation. 3. The anterior stalk of the thalamic radiation (Figs. 588 and 590) arises in the lateral nucleus, passes to the frontal portion of the internal capsule, and reaches the inferior and middle frontal convolutions, the anterior portion of the superior frontal convolution, and the middle of the gyrus fomicatus (Santee). The anterior stalk of the thalamic radiation, plus the ansa lenticularis and the ansa peduncularis, constitutes the cortical fillet or the three systems of Flechsig (p. 915). 4. The posterior stalk of the thalamic radiation (Fig. 590) is called the optic radiation (radiatio cocpitothalamica). The afferent part arises in the pulvinar and the external geniculate body, passes through the internal capsule, and terminates in the occipital cortex. The efferent portion terminates in the superior quadrigeminal body. 5. The acoustic radiation (Fig. 590) arises about the internal geniculate body, passes through the internal capsule, and reaches the auditory region in the temporal cortex.

The Pineal Body, Epiphysis Cerebri, Conarium, or Pineal Gland (corpus pineale) (Figs. 584 and 587).—The pineal body or gland, so named from its peculiar shape (pinus, a fir-cone), is a small reddish-gray body, conical in shape (hence its synonym, conarium), placed immediately above and behind the

---

1 Anatomy of the Brain and Spinal Cord. By Harris E. Santee. 2 Ibid. 3 Ibid.
posterior commissure and between the anterior corpora quadrigemina, on which it rests. It is covered by the velum interpositum, which intervenes between it and the splenium of the corpus callosum. It is an upgrowth from the second cerebral vesicle (hence the name epiphysis), and is at first hollow, but soon becomes solid and loses its connection with the ventricular cavity. It is retained in its position by a duplicature of pia mater, derived from the under surface of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length and from two to three in width at its base, and is said to be larger in the child than in the adult, and in the female than in the male. It is attached on either side by a flattened stalk or peduncle of white matter, the pedunculus conarii (habenula). This stalk consists of two laminae, upper and lower, separated by a little recess, the pineal recess (recessus pinealis). The lower lamina is prolonged into the posterior commissure. The upper divides into two strands, the peduncles of the pineal gland (striae pinealis); these extend on either side along the optic thalamus at the junction of its mesial and upper surfaces to the anterior pillars of the fornix, with which they blend. The two stalks join together at their posterior extremity, in front of the pineal gland, forming a sort of festoon, and the base of the gland is connected to their posterior margin at the point of junction.

Structure.—The pineal gland consists of a number of follicles, lined by epithelium, and connected together by ingrowths of connective tissue. The follicles contain a transparent viscid fluid and a quantity of sabulous matter named brain sand (acervulus cerebri), composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are present at all periods of life. They are found upon the surface of the pineal body and occasionally upon its peduncles.

 Morphologically the pineal gland is regarded as the homologue of the structure termed the pineal eye of the lizards. In these reptiles the epiphysis cerebri is attached by an elongated stalk and projects through the parietal foramen. Its extremity lies immediately under the epidermis, and on microscopic examination presents, in a rudimentary fashion, structures similar to those found in the eyeball.

III. The Mid-brain (Mesencephalon) (Figs. 557, 584, 585, 587).

The mid-brain is the short and constricted portion of the brain which lies in the opening of the tentorium cerebelli (incisura tentorii) and which connects the pons Varolii with the inter-brain and hemispheres, and hence it is frequently called the isthmus cerebri (isthmus rhombencephali). It is developed from the third cerebral vesicle, the cavity of which becomes the aqueduct of Sylvius. It comprises the crura cerebri, the corpora quadrigemina, the geniculate bodies, and the Sylvian aqueduct. Its direction is from before backward and downward. In front and above it is continuous with the inter-brain; below with the pons. Its two surfaces are ventral and dorsal. They are free, but concealed: the ventral surface by the apices of the temporal lobes which overlap it; the dorsal, by the overhanging cerebral hemispheres. The ventral surface, when exposed by drawing aside the temporal lobes, is seen to consist of two cylindrical bundles of white matter which emerge from the pons and diverge as they pass forward and outward to enter the inner and under part of either hemisphere. They are the cerebral peduncles (crura cerebri), and between them is a triangular area, already described as part of the interpeduncular space (fossa interpeduncularis) (see pp. 884 and 885); near the point of divergence of the crura the roots of the third nerve are seen to emerge in several bundles from a groove, the sulcus oculomotorius (sulcus nervi oculomotorii) (Fig. 570). The dorsal surface (Fig. 584) is not visible until a considerable portion of the cerebral hemispheres and other overlying structures have
been removed. It then presents four rounded eminences placed in pairs, two in front and two behind, and separated from one another by crucial depression. These are termed the corpora quadrigemina (tubercula quadrigemina) (Figs. 584 and 585). The ventral and dorsal surfaces meet on the side of the mid-brain, and are separated from each other by a furrow, the lateral groove (sulcus lateralis mesencephali), which runs from below upward and forward (Fig. 585).

If a cross-section be made through the mesencephalon (Fig. 585), it will be seen that each lateral half is divided into two unequal portions by a lamina of deeply pigmented gray matter, named the substantia nigra. The postero-superior portion of the crus is named the tegmentum, and the antero-inferior the crista or pes. The substantia nigra is curved on section with its concavity upward, and extends from the lateral groove externally to the oculomotor sulcus internally. The two crustae are in contact in front of the pons, from which point they diverge from one another, but the two halves of the tegmentum are joined to each other in the mesial plane by a prolongation forward of the raphé or median septum of the pons. Laterally the tegmenta are free, but dorsally they blend with the corpora quadrigemina.

Crista or Pes (basis pedunculi) (Fig. 585).—

The crista is known as the pes of the crus cerebri. The crustae are two in number, are semilunar on section, and are separated by the interpeduncular space (Fig. 570). From the front of the pons each crista passes upward, forward, and outward, enters the cerebrum to the outer side of the thalamus, and its fibres enter and spread out in the internal capsule (Figs. 589 and 590). The great bulk of the fibres are limited to the superior lamina of the capsule. The deep portion of the crista contains the intermediate bundle or tract (Fig. 590), the fibres of which rise in the corpus striatum and terminate in motor cranial nuclei and the nucleus pontis, and from this nucleus fibres pass by way of the middle peduncle of the cerebellum to the cortex of the opposite cerebellar hemisphere.

The superficial portion of the crista contains three sets of fibres (Figs. 589 and 590): 1. The outer one-fifth is composed, according to Dejerine, of fibres which take origin in the cortex of the superior, middle, and inferior temporal convolutions, the cerebro-cortico-pontal tract (tractus cerebrocorticopontalis temporalis). They pass through the inferior lamina of the internal capsule and through a portion of the superior lamina, and mostly terminate in the nucleus pontis. Some few of these fibres terminate in the motor nuclei of the cranial nerves. 2. The middle three-fifths, which is largely composed of motor fibres, is known as the pyramidal tract (fasciculus longitudinalis pyramidalis). These fibres take origin in the cells of the Rolandoic area of the cortex, converge to the internal capsule, and pass down through its genu and through the anterior two-thirds of its posterior limb to the crista, from which they are prolonged as longitudinal fibres through the ventral portion of the pons and as the pyramid through the medulla. Below the medulla they pass into the direct and crossed pyramidal tracts of the spinal cord. The median portion of the pyramidal tract occupies the genu of the internal capsule and passes to the muscles of the face and the muscles of speech. The fibres which pass to the arm muscles, in the crista, are posterior and external to the fibres which go to the face. Behind and external to the arm fibres are the fibres to the muscles of the trunk.

1 Spitzka; Santee.
and leg. A few fibres from the cerebellum are placed among the pyramidal fibres. These fibres reached the pons by way of the middle cerebellar peduncle, ascend from the pons with the longitudinal fibres, and reach the crusta. 3. The inner one-fifth of the crusta is formed by the fibres of the median fillet (lemniscus medialis) and motor fibres coming from the cortex in front of the Rolandoic fissure (from the prefrontal lobe). This tract from the prefrontal lobe descends through the anterior limb of the internal capsule and through the crusta and reaches the nucleus pontis, from which point it is connected by fibres with the cerebellar hemisphere of the opposite side. It is called the frontal cerebro-cortico-pontal tract (tractus cerebrocorticopontalis frontalis). The median fillet is composed of central sensory fibres from the spinal nerves and all the cranial nerves, except the cochlear branch of the auditory (Santee). It arises from the fillet, and at the lower part of the crusta is situated at the mesial border. As it ascends it courses obliquely outward to meet the lateral border of the pyramidal tract. It enters the sub-thalamic region, and ends in the lateral nucleus of the optic thalamus. Some of the fibres of this tract reach the cortex by joining the ansa peduncularis and the ansa lenticularis.

The Tegmentum (Fig. 585).—The tegmentum (the cover) is that portion of the mid-brain which is superior to the substantia nigra and covers the two crustae and the substantia nigra. Its ventral surface is placed within the concave surface of the substantia nigra. The internal geniculate bodies and the corpora quadrigemina are upon its dorsal surface. The anterior extremity of the tegmentum enters the optic thalami, and the posterior extremity is continued into the pons. The tegmentum contains the aqueduct of Sylvius (p. 912 and Figs. 585 and 587).

Fibres of the Tegmentum (Fig. 590).—The pontine formatio reticularis, the gray matter of the floor of the fourth ventricle, and the longitudinal fibres of the dorsal portion of the pons are continued and compose the tegmentum, which structure has upon its dorsal aspect the geniculate and quadrigeminal ganglia. Each half of the tegmentum consists of strands of longitudinal white fibres separated from each other by transversely arched fibres. There is also a considerable quantity of gray matter. The peculiarly reticulated structure formed by the gray and white matter is named the formatio reticularis, and is similar to the structure met with in the pons and medulla, with which it is continuous.

The Red Nucleus of the Tegmentum (nucleus tegmenti) (Fig. 589).—The red nucleus of the tegmentum is a tract of gray matter situated partly in the tegmentum and partly in the subthalamic tegmental region on either side of the middle line. It is composed of numerous large cells which are deeply pigmented. It is pierced by the fibres of the third nerve. The red nucleus sends fibres to the corpus dentatum by means of the opposite superior peduncles of the cerebellum, and also gives off the crossed descending tract. The nucleus of Luys (nucleus hypothalamicus) is above and external to the red nucleus and between it and the crusta. It receives fibres from the median fillet and from the corpus striatum, and is connected by fibres to the lamina cinerea and tuber cinereum, which are known as the commissure of Meynert (Santee).

The longitudinal fibres in some parts of the tegmentum are arranged in six fairly well-defined tracts, which are described as follows by Harris E. Santee in the Anatomy of the Brain and Spinal Cord:

1. The Posterior Longitudinal Bundle (fasciculus longitudinalis medialis) (Fig. 586) is in large part a tract of the aqueduct. It lies by the side of the raphé just below the aqueduct. These fibres ascend from the gray substance of the anterior cornu of the spinal cord. In the anterior column of the cord they probably form short longitudinal commissures between different segments of the cord. They ascend through the pyramid of the medulla, form the posterior longitudinal bundle of the
pons, and enter the tegmentum. The posterior longitudinal bundle, while traversing the pons, receives fibres from the cerebellum, and in the pons and medulla receives fibres from the sensory nuclei of cranial nerves. "It carries motor fibres from the sixth to the third nerve; also descending motor fibres from the nucleus of the motor oculi to the genu of the seventh or facial nerve." Soon after entering the tegmentum the posterior longitudinal bundle decussates across the raphé with the bundle of the opposite side. This constitutes the lower decussation, and the decussated fibres pass to the nuclei of the third, fourth, and other cranial nerves. The undecussated fibres ascend, and in the posterior commissure decussate. This is known as the upper decussation, and the fibres enter "the pineal body and stratum dorsale of the hypothalamic region."

2. The **Anterior Longitudinal Bundle** is composed of fibres which pass from the superior quadrigeminal body to the ciliary centre (dilator fibres of the pupil) and other centres in the spinal cord.

3. The **Fillet** or **Lemniscus** is "a segment in the direct sensory tract. It carries spinal and cranial impulses to the corpora quadrigemina and optic thalamus." It takes its chief origin from the medulla, and passes through the formatio reticularis of the pons to the ventral portion of the tegmentum, where it divides into two portions, the **interolivary fillet** and the **lateral fillet**.

The **interolivary fillet** (*lemniscus interolivaris*) arises from the opposite side of the medulla oblongata (from the nucleus gracilis and nucleus cuneatus), decussates with the sensory fibres, and terminates in the lateral nucleus of the thalamus. A bundle of fibres come off from the interolivary fillet soon after its origin and
passes to the superior quadrigeminal bodies. This bundle is the upper or superior fillet (lemniscus superior). The interolivary bundle after giving off the superior fillet is known as the median or mesial fillet (lemniscus medialis or mesialis). It ascends, turns toward the ventral surface of the tegmentum, passes through the substantia nigra, and along the inner one-fifth of the crista to the thalamus, and from the thalamus connection with the cortex is established by the ansa lenticularis and the ansa peduncularis.

The lower or lateral fillet (lemniscus lateralis) arises almost entirely from the cochlear nuclei, and mostly from the opposite nucleus. It is situated in the ventral part of the tegmentum, through which it passes obliquely and emerges at its side, and after crossing the superior peduncle of the cerebellum, passes to the inferior quadrigeminal bodies. It is reinforced by some fibres from the superior medullary velum. It is a path in the conduction of auditory impressions. These impressions pass from the auditory nerve to the lateral fillet, from this to the inferior brachium, and then to the cortex by the acoustic radiation (Fig. 590).

4. The Superior Peduncle of the Cerebellum (brachium conjunctivum) (Figs. 590 and 599) ascends from the dorsal surface of the pons. It is connected to its fellow peduncle by a band of white matter called the valve of Vieussens (velum medullare anterius) (Fig. 584). The fibres of the superior peduncles of the cerebellum pass beneath the quadrigeminal bodies, and to a large extent decussate across the raphé and below the Sylvian aqueduct. It is thus evident that the fibres from one-half of the cerebellum pass largely to the opposite half of the cerebrum. The numerous crossed and the few uncrossed fibres pass forward, enclosing the red nucleus (in which structure many of the fibres terminate and from which structure it obtains some fibres), and passes to the “stratum dorsale of the hypothalamic region.”

5. The Olivary Fasciculus (fasciculus tegmenti centralis) (Fig. 589) arises from the inferior olivary nucleus of the medulla, ascends through the medulla and pons to the tegmentum, passes through the decussation of the superior peduncles of the cerebellum, and ascends to the outer side of the posterior longitudinal bundle of terminal fibres, to end in the lenticular nucleus.

6. The Crossed Descending Tract arises in the red nucleus (Fig. 589), decussates with the opposite tract, enters the lateral fillet, reaches the medulla, where it “mingles with the antero-lateral ascending cerebellar tract,” and passes into the pyramidal tract of the cord, to end in “the lateral horn and centre of the gray crescent.” The nucleus of Luys (Fig. 589) is the anterior termination of the substantia nigra.

The Substantia Nigra (Figs. 585 and 589).—This, as already stated, constitutes the central portion of the mid-brain. It is a layer of deeply pigmented gray matter, which separates the crista below from the tegmentum above. It can be seen at the base of the brain between the crista. In this region it is known as the posterior perforated lamina (substantia perforata posterior) (Fig. 570). In each lateral sulcus the edge of the substantia nigra reaches the surface (Fig. 585). The substantia nigra extends from the pons behind to the corpora albae and nucleus of Luys in front. It is thicker internally than externally, where it is partially divided up by the mesial fillet passing from the tegmentum to the crista. It is traversed at its inner part by some of the fibres of origin of the third cranial nerve, which emerge from the motor oculi groove. The cells are small and multipolar, and are characterized by containing a large amount of dark pigment granules.

The Interpeduncular Ganglion (ganglion interpedunculare) is just in front of the pons in the median line. Some fibres (the fasciculus retroflexus) (Fig. 586) join this ganglion to the nucleus habenulae of the thalamus (Forel, Santée). In each half of the substantia nigra, laterally and anteriorly, is a nucleus known as the nucleus of Luys (nucleus hypothalamicus) (Fig. 589). The zona incerta separates the nucleus of Luys from the red nucleus of the tegmentum.
The Corpora or Tubercula Quadrigemina (Figs. 574, 584, 585, 586, and 587).—The corpora or tubercula quadrigemina are four rounded eminences placed in pairs, two in front and two behind, and separated from one another by the crucial groove or depression. They are situated on the dorsal surface of the mid-brain, immediately behind the third ventricle and posterior commissure, and beneath the splenium of the corpus callosum. The anterior or upper pair (colliculi superiores), called the nates, are the larger. They are oval, their long diameter being directed forward and outward, and are of a gray color. The posterior or lower pair (colliculi inferiores), called the testes, are hemispherical in form, and lighter in color than the preceding. From the outer side of each of these eminences a prominent white band, termed the brachium, is continued forward and outward. The band from the nates (brachium quadrigeminum superius) passes obliquely outward between the pulvinar and the inner-geniculate bodies into the external geniculate body. The band from the testes (brachium quadrigeminum inferius) loses itself beneath an oval prominence on the side of the quadrigeminal body. This prominence is called the internal geniculate body. The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds they are hollow, and only two in number (corpora bigemina); they represent the anterior quadrigeminals of mammals. In these lower animals the corpora bigemina are frequently termed the optic lobes, because of their connection with the optic tracts. In the mammalia the corpora are four in number, and solid. In the human foetus all four bodies are differentiated by the fifth month, and form at this time a considerable proportion of the brain. In man the anterior quadrigeminal bodies are sometimes called the optic lobes and the posterior bodies the auditory lobes.

Structure.—The corpora quadrigemina are composed of white matter externally, and gray matter within. The posterior pair consist almost entirely of gray matter, covered over by a very thin stratum of white substance. Beneath the gray matter is a thin layer of white fibres, forming a part of the lower fillet. This separates the gray matter of the posterior corpora quadrigemina from the central gray matter of the aqueduct. The anterior pair are covered superficially by a thin stratum of white matter. The stratum zonale, the fibres of which are fine and arranged transversely. Beneath this is the stratum cinereum, a layer of gray matter which resembles a cup, semilunar in shape, thicker in the centre, and thinning off toward the margins, and consisting of numerous multipolar cells, for the most part of small size, embedded in a fine network of nerve-fibres. Below this again is the stratum opticum or upper gray-white layer, characterized by the large amount of fine nerve-fibres which intersect the gray matter. These fibres vary in size in different parts of the layer, but have for the most part a longitudinal direction. The nerve-cells between the fibres are larger, and send their axis-cylinder processes into the next stratum. Finally there is the stratum lemnisci, or deep gray-white layer, which separates the rest of the quadrigeminal body from the gray matter around the aqueduct. It consists of fibres partly derived from the upper fillet and partly from the cells of the preceding layer. Interspersed among these fibres are nerve-cells of large size.

The anterior quadrigeminal body contains an anterior layer of longitudinal fibres, which takes origin in close relation to the optic fibres and ends in the ciliary centre of the spinal cord. In the posterior quadrigeminal body the white fibres are continuous posteriorly with the lateral fillet, and are continuous laterally with the brachium. The anterior quadrigeminal bodies “associate optic fibres with the nuclei of the third, fourth, and sixth cranial nerves and with the cilio-spinal centre in the cervical cord” (Santee). The posterior bodies constitute “a way-station in the auditory conduction path” (Santee) (Fig. 590).

The Corpora Geniculata.—The corpora geniculata are two small, oblong masses on each side, situated behind and beneath the posterior end of the optic
thalamus, and named, from their position, external and internal geniculate bodies. These two bodies are separated from each other by the brachium anterius of the anterior quadrigeminal body. It is convenient and customary to describe these two bodies together, but the student should bear in mind that the corpus geniculatum externum belongs in reality to the optic thalamus; the corpus geniculatum internum, which is part of the tegmentum, alone belonging to the mid-brain.

The External Geniculate Body (corpus geniculatum laterale) (Fig. 613).—The external geniculate body is of a dark color, and presents a laminated arrangement, consisting of alternate layers of gray and white matter. Its cells are large, multipolar, and pigmented; their processes are intimately related with the visual area in the cerebral cortex of the occipital region (Fig. 590). It is believed that the intercellular gray matter of these bodies is composed, to a considerable extent, of the terminations of the optic nerve, which form synapses around the cells. About 80 per cent. of the optic fibres enter the external geniculate body (von Monokow, Santee). It is, in fact, the termination of the outer root of the optic tract.

The Internal Geniculate Body (corpus geniculatum mediale) (Fig. 613).—The internal geniculate body is the termination of the inner root of the optic tract. It seems to receive some of the fibres of the optic tract and is “a way-station in the auditory tract” (Santee). It is smaller in size and lighter in color than the external geniculate body, and does not present a laminated arrangement. It receives the posterior brachium from the inferior quadrigeminal body. The internal geniculate bodies are connected with each other through the optic commissure by a band of intercerebral fibres of the optic tract named Gudden’s commissure. The anterior quadrigeminal body, the pulvinar, and the external geniculate body are intimately concerned with vision. They constitute the lower cerebral centre for the optic nerve-fibres which end in them. Extirpation of the eyes in newly born animals entails an arrest of their development, but has no effect on the posterior quadrigeminal body or the internal geniculate body. These latter also are well developed in the mole, in which animal the superior quadrigeminal body is rudimentary.

The Aqueduct of Sylvius or Iter a Tertio ad Quartum Ventriculum (aqueductus cerebri) (Figs. 574, 584, 585, and 587).—This is a narrow canal, about

---

Fig. 587.—Median section through the third and fourth ventricles, left half. M.C., middle commissure. (Testut.)
half an inch in length and from one-sixteenth to one-eighth of an inch in height, situated between the corpora quadrigemina and the tegmentum, and connecting the third with the fourth ventricle. Its shape on transverse section varies, being T-shaped below, triangular above, and oval about the middle of its course. It is lined by columnar ciliated epithelium, and is surrounded by a layer of gray matter, called the central gray matter of the aqueduct, which is continuous with the gray matter of the third and fourth ventricles. This gray matter is separated above from that of the corpora quadrigemina by the stratum lemnisci; below the central gray matter lie the posterior longitudinal bundle and the formatio reticularis of the tegmentum. The central gray matter is more abundant below the canal than above it. In the gray matter are certain defined groups of cells, which are the nuclei of the third and fourth cranial nerves.

Subthalamic Region.—One other structure, to which allusion has already been made, requires mention in this connection; it is the subthalamic region. It is a prolongation forward of the tegmentum of the crus cerebri, which becomes continuous with the lower surface of the optic thalamus. Toward the anterior part of the crus cerebri the tegmentum becomes thinned out, and is blended with the superfine portion of the optic thalamus. To this region, the name subthalamic tegmental region has been given. In front it is lost at the base of the brain in the gray matter of the anterior perforated space, and is continuous with the gray matter of the floor of the third ventricle. The subthalamic tegmental region contains a forward prolongation of the red nucleus, and consists from above downward of three layers: (1) stratum dorsale, which is directly applied to the under surface of the optic thalamus, and consists of fine longitudinal fibres; (2) the zona incerta, a continuation forward of the formatio reticularis of the tegmentum; and (3) the corpus subthalamicum or the nucleus of Luys (nucleus of Luys or nucleus hypothalamicus), a mass of gray matter which on section presents a lenticular shape, and is the termination of the substantia nigra.

Structure of the Cerebrum.—The cerebrum, like the other parts of the great nerve centre, is composed of gray and white matter. In order to give some general idea of its construction, at all events in part, it may be compared, for the sake of illustration, to a tree, the trunk of which divides into two main divisions, and these break up into smaller branches, which finally end in twigs, to which are attached the leaves, forming an investment to the branches and covering the whole tree. The trunk is represented by the medulla oblongata as it passes through the foramen magnum; the two main divisions by the crura cerebri, which break up into smaller branches; these diverge from each other, divide and subdivide, until they reach the surface of the hemispheres, where they terminate in single nerve-fibres, which are continuous with the basal axial cylinder processes of the nerve-cells, the representatives of the leaves. These cells are arranged on the surface, covering the hemispheres like a cap, and constitute the cerebral cortex. But here the analogy ends, for in the cerebrum there are, in addition to this cortex, other masses of gray matter situated in the middle of the brain; and other white fibres besides the diverging ones that have been mentioned, and which serve either to connect the two cerebral hemispheres, or to unite different structures in the same hemisphere.

The White Matter of the Cerebrum.—The white matter of the cerebrum consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course they take. 1. Projection or peduncular fibres (Figs. 588, 589, and 590), which connect the hemisphere with the medulla oblongata and cord. 2. Transverse or commissural fibres (C.C. in Fig. 588), which unite together the two hemispheres. 3. Association fibres (Figs. 591 and 592), which connect different structures in the same hemisphere. Many of the association fibres are collateral

Page 913
branches of the projection fibres, but others are the axones of independent cells.

1. The Projection or Peduncular Fibres (Figs. 588, 589, and 590) are either centrifugal (motor) or centripetal (sensory), and they connect the cerebral cortex with every portion of the body, and either project impulses from the cortex to every portion of the body or bring impressions from all parts to the cortex. The basal ganglia intercept many projection fibres, especially centripetal fibres. The projection fibres are composed first of the "medullated axis-cylinders of the large and medium-sized pyramids and a few of the polymorphous neurones in the cerebral cortex; and second, of medullated axones of neurones whose centres are situated in masses of gray matter below the cerebral cortex." These fibres form in the hemisphere the corona radiata and the internal capsule, and in the mid-brain the crus. The fibres of the crus are arranged in two strata, the ventral or superficial stratum or crista and the dorsal or deep stratum or tegmentum. Between the two strata is the substantia nigra.

The Centrifugal or Motor Projection Fibres.—Most of the motor fibres are included in the crus. The deep portion of the crus is composed of the intermediate bundle or tract (p. 907), and the superficial portion of the crus is composed of three sets of fibres (p. 907): 1. The temporal cerebro-corticopontal tract (tractus cerebrocorticopontalis temporalis), occupying the outer one-fifth of the crus. 2. The pyramidal tract (fasciculus longitudinalis pyramidalis), occupying the middle three-fifths of the crus. These fibres pass to the pyramid of the medulla and to the direct and crossed pyramidal tracts of the spinal cord. A few fibres from the cerebellum are placed among the pyramidal fibres. They reach the pons by way of the middle cerebellar peduncle, ascend from the pons with the longitudinal fibres, and reach the crista. 3. The inner one-fifth of the crista is formed by the median fillet and motor fibres coming from the cortex in front of the Rolandic fissure. The tegmentum contains some few motor fibres arranged in several bundles—viz., the anterior longitudinal bundle, a portion of the superior peduncle of the cerebellum: the descending or motor root of the fifth nerve, the crossed descending tract from the red nucleus. To these previously mentioned motor fibres in the tegmentum, Santee adds "certain fibres in the formatio reticularis."

The Centripetal or Sensory Projection Fibres.—In the tegmentum are the sensory fibres, some of the fibres of the formatio reticularis, some of the fibres of the posterior longitudinal bundle, the fillets, most of the fibres of the superior cerebellar peduncle, the outer root of the optic tract, and the olivary fasciculus. Nearly all of the bundles terminate in the basal ganglia, "but the paths of con-

---

1 Anatomy of the Brain and Spinal Cord. By Harris E. Santee.
2 Ibid.
duction are continued through the internal capsule” (Santee). In the internal capsule the sensory projection fibres comprise the three systems of Flechsig (the cortical fillet), the optic radiation, and the acoustic radiation.

The Three Systems of Flechsig.—The chief origin of the three systems of Flechsig is in the lateral nucleus of the thalamus. The first system of Flechsig is composed of fibres of common sensation and is called the ansa peduncularis. It passes from the thalamus to the cortex of the ascending frontal and parietal convolutions. The fibres of this first system are in the inferior lamina of the internal capsule, and are posterior to the pyramidal tract. Some fibres of the ansa peduncularis pass through the lenticular nucleus, others pass through the external capsule, but all of them terminate as do those in the internal capsule, in the cortex. The second system of Flechsig is called the ansa lenticularis. Its fibres convey impressions of common sensation. It arises from the thalamus at a higher level than the ansa peduncularis, and in the internal capsule its fibres are among the pyramidal fibres. It terminates in the cortex about the central convolution, the superior frontal convolution, the paracentral lobule, and the limbic lobe. Some fibres pass through the internal capsule to the lenticular nucleus and aid in forming the external capsule. The third system of Flechsig is the anterior stalk of the thalamic radiation. It arises in the thalamus, passes to the frontal portion of the internal capsule, and reaches the inferior, middle, and superior frontal convolutions and the gyrus fimbriatus. The third system also conveys common sensory impressions.

The optic radiation (D in Fig. 590) takes origin in the pulvinar of the thalamus and in the external corpus geniculatum. The fibres pass back of the lenticular nucleus and reach the cortex of the cuneate lobe, in which region the corresponding half of each retina is represented.

The acoustic radiation (D in Fig. 590) with the inferior brachium from the inferior quadrigeminal body, according to Barker, constitute the continuation of
the auditory path "from the end of the lateral fillet, in the inferior quadrigeminal body, to the internal geniculate body, and then, through the retro-lenticular part of the internal capsule, to the transverse temporal gyri and the third and fourth fifths of the superior temporal convolution."

2. The Transverse or Commissural Fibres (Figs. 572, 573, and C.C. in Fig. 588) connect the two hemispheres. They include: (a) the transverse fibres of the corpus callosum (p. 886); (b) the anterior commissure (p. 896); (c) the posterior commissure (p. 903), and have already been described.

3. The Association Fibres (Figs. 591 and 592) connect different structures in the same hemispheres, and are in or near to the cortex. They take origin from the small pyramidal and polymorphous cells of the deep layer of the cortex. Their direction is parallel to the surface of the hemisphere, and in their course they cross the projection and commissural fibres. They are of two kinds: (1) those which unite adjacent convolutions, short association fibres; (2) those which pass between more distant parts in the same hemisphere, long association fibres.

The short association fibres are situated immediately beneath the gray substance of the cortex of the hemispheres, and connect together adjacent convolutions. They constitute subcortical tracts and are divided into arcuate fibres and tangential fibres. Some of these fibres connect the "visual sensory area with the visual memory area, and the auditory sensory with the auditory memory area." 2

The long association fibres associate cerebral centres which are far apart. They are gathered into bundles and dip down deep into the centrum ovale. They

1 Anatomy of the Brain and Spinal Cord, by Harris E. Santee
2 Ibid.
include the following: (a) the uncinate fasciculus; (b) the cingulum; (c) the superior longitudinal fasciculus; (d) the inferior longitudinal fasciculus; (e) the perpendicular fasciculus; (f) the fornix; (g) the occipito-frontal fasciculus.

(a) The Uncinate Fasciculus (fasciculus uncinatus) (Fig. 592).—The uncinate fasciculus passes across the bottom of the Sylvian fissure and connects the uncinate convolution with the orbital portion of the frontal lobe. Barker points out that this fasciculus joins the third frontal, internal orbital, and posterior orbital convolutions with the limbic lobe.
(b) The Cingulum or the Fillet of the Gyrus Fornicatus (Fig. 592) is a band of white matter which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forward and upward parallel with the rostrum, wind around the genu, runs in the convolution from before backward, immediately above the corpus callosum, turns around its posterior extremity, and passes into the Hippocampus major, through which it courses to its anterior extremity. According to Beem there are three sets of fibres in the cingulum. The anterior fibres join the internal olfactory root and the anterior perforated lamina with the front of the frontal lobe. The horizontal fibres join the gyrus fornicatus with the frontal lobe. The posterior fibres join the fusiform convolution (the fourth temporal) with the hippocampal convolution and the temporal lobe.1

(c) The Superior Longitudinal Fasciculus (fasciculus longitudinalis superior) (Fig. 592).—The superior longitudinal fasciculus is beneath the convex surface of the hemisphere. It joins the frontal cortex with the parietal and temporal cortex and brings into relation the motor speech centres and the centres of auditory and visual memories.

(d) The Inferior Longitudinal Fasciculus (fasciculus longitudinalis inferior) (Fig. 592).—The inferior longitudinal fasciculus associates the centres of auditory and visual memory. It is a collection of fibres which connects the temporal and occipital lobes, running along the outer wall of the descending and posterior cornu of the lateral ventricle.

(e) The Perpendicular Fasciculus or Fasciculus Rectus (Fig. 592).—The perpendicular fasciculus runs vertically in front of the occipital lobe, and connects the inferior parietal lobule with the second and third temporal convolutions, and also connects the superior occipital convolution with the inferior occipital and the fourth temporal convolutions.

(f) The Fornix (corpus fornicis) (Fig. 586).—The fornix by its anterior pillar is connected with the corpus albicans and by means of the bundle of Vicq d'Azyn with the optic thalamus. Most of the posterior pillar ends in the hippocampus major, but some of the fibres (the corpus fimbriatum) go to the uncinate convolution. Through the fibres of the lyra it probably also unites the opposite hippocampal convolutions.

(g) The Occipito-frontal Fasciculus of Forel (fasciculus occipitofrontalis) (Fig. 592).—The occipito-frontal fasciculus is placed between the cingulum and the superior longitudinal fasciculus. It connects the frontal cortex with the occipital cortex. Some regard it as a part of the corpus callosum.

The Gray Matter of the Cerebrum.—The gray matter of the cerebrum, in accordance with its situation, is disposed in three great groups: (1) The gray matter of the cerebral cortex or cortical gray matter. (2) The gray matter of the ganglia or ganglionar gray matter. (3) The central or ventricular gray matter.

The Gray Matter of the Cortex.—The cortex, bark or envelope of the cerebrum, is a thin layer of gray matter on the surface, which encompasses the white matter of the hemispheres (centrum ovale). The cortex has been mapped out into definite areas and centres, each of which is connected with a well-defined function (p. 952).

On examining a section through one of the convolutions of the Rolandic area with a lens, it is seen to consist of alternating white and gray layers thus disposed from the surface inward: (1) a thin layer of white substance; (2) a layer of gray substance; (3) a second layer of white substance (outer band of Baillarger or band of Gennari); (4) a second gray layer; (5) a third white layer (inner band of

1 Anatomy of the Brain and Nervous System. By Harris E. Santee.
Baillarger); (6) a third gray layer, which rests on the medullary substance of the convolution.

The cortex is made up of nerve-cells which vary in size and shape, and of nerve-fibres, some of which are medullated, but most of which are non-medullated, embedded in a matrix of neuroglia.

The nerve-cells in a typical section of the cortex are arranged in five layers (Fig. 593), named from the surface inward as follows: (1) the molecular layer; (2) the layer of small pyramidal cells; (3) the layer of large pyramidal cells; (4) the layer of polymorphous cells; (5) the layer of fusiform cell-bodies (Santee) (not shown in Fig. 593).

The Molecular, the Superficial or the Neuroglia Layer.—This layer is immediately adjacent to the pia mater. Neuroglia constitutes the greatest amount of the superficial layer; hence its other name of neuroglia layer. In this layer the cells are irregular and are known as the neurones of Cajal. The cells are polygonal, triangular, and fusiform in shape, and are associative in function. Each polygonal cell gives off some four or five dendrites, while its axones may arise directly from the cell or from one of its dendrites. The axones and dendrites of these cells ramify in the molecular layer. Each triangular cell gives off two or three dendrites, from one of which the axone arises, the dendrites and the axone ramifying in the molecular layer. The fusiform cells are placed with their long axes parallel to the surface and are mostly bipolar, each pole being prolonged into a dendrite, which runs horizontally for some distance and furnishes ascending branches. Their axones, two or three in number, arise from the dendrites, and, like them, take a horizontal course, giving off numerous ascending collaterals. The distribution of the axones and dendrites of all three sets of cells is limited to the molecular layer.

Besides the neuroglia, the cells, and the gray fibres, this layer contains medullated nerve-fibres arranged in a network and constituting the superficial white layer.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in the second and third layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axone, and this passes into the central white substance, giving off collaterals in its course, and is distributed as a projection, commissural, or association fibre.
Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen, when prepared by the silver or methylene-blue method, to be studded with projecting bristle-like processes. The larger pyramidal cells, especially in the Rolandic area, may exceed 50 μ in length and 40 μ in breadth, and are termed giant cells. The chief function of the small pyramids is commissural and associative. The chief function of the large pyramids is motor, but they have also commissural and associative functions.

Layer of Polymorphous Cells.—The cells in this layer, as their name implies, are very irregular in contour, the commonest varieties being of a spindle, star, oval, or triangular shape. Their dendrites are directed outward, toward, but do not reach, the molecular layer; their axones pass into the subjacent white matter. From this layer come commissural fibres, long association fibres, and some projection fibres.

There are two other kinds of cells in the cerebral cortex, but their axones pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (a) the cells of Golgi, the axones of which do not become medullated, but divide immediately after their origin into a large number of branches, which are directed toward the surface of the cortex; (b) the cells of Martinotti, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axones pass out into the molecular layer and form an extensive horizontal arborization.

Layer of Fusiform Cell-bodies.—It receives the name of the claustrum formation, because it is formed like the claustrum. This layer is not sharply defined from the white matter beneath; the change from one to the other is gradual. The long axes of most of the cells are perpendicular to the surface of the hemisphere, but beneath the fissures they are parallel to the surface (Santee). “The commissural and long association fibres belong, for the most part, to the fusiform and polymorphous neurones.”

Nerve-fibres.—These fill up a large part of the intervals between the cells. Some of these fibres form fasciculi; some are isolated, and others are arranged in plexuses. They may be medullated or non-medullated—the latter comprising the axones of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse, the transverse tangential or horizontal fibres, or vertical, the vertical or radial fibres. The transverse fibres run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They consist of several strata, of which the following are the most important: (1) a stratum of white fibres covering the superficial aspect of the molecular layer; (2) the band of Bechterew, found in certain parts of the superficial portion of the layer of the smaller pyramidal cells; (3) the external or outer band of Baillarger or the band of Gennari, which runs through the layer of large pyramidal cells; (4) the internal band of Baillarger, which intervenes between the layer of large pyramidal cells and the polymorphous layer. According to Cajal, the transverse fibres consist of (a) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (b) the arborizations of the axones of Golgi’s cells; (c) the collaterals and terminal arborizations of the projection, commissural, or association fibres. The vertical fibres.—Some of these—viz., the axones of the pyramidal and polymorphous cells—are directed toward the central white matter, while others, the terminations of the commissural, projection, or association fibres, pass outward to end in the cortex. The axones of the cells of Martinotti are also ascending fibres.

In certain parts of the cortex this typical structure is departed from. The chief
of these regions are: (1) the occipital lobe, (2) the hippocampus major, (3) the dentate convolution, and (4) the olfactory bulb.

Special Types of Gray Matter. 1. The Occipital Lobe.—In the cuneus and the calcarine fissure of the occipital lobe, Cajal has recently described as many as nine layers. Here the inner band of Baillarger is absent; the outer band of Baillarger or band of Gennari is, on the other hand, of considerable thickness. If a section be examined microscopically, an additional layer is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axone arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like cells with ascending axones, the cells of Martinotti. This area of the cortex forms the visual centre, and it has been shown by Dr. J. S. Bolton 1 that in old-standing cases of optic atrophy the thickness of Gennari’s band is reduced by nearly 50 per cent.

2. The Hippocampus Major.—In the hippocampus major the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (a) S. convolutum or S. granulosum, containing many tangential fibres; (b) S. lacunosum, presenting numerous lymphatic or vascular spaces; (c) S. radiatum, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and the cells are mostly of large size. The axones of the cells in the polymorphous layer may run in an ascending, descending, or horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus.

3. The Dentate Convolution.—In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

4. The Olfactory Bulb.—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the cavity of the lateral ventricle. In man the original cavity is filled up by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white matter, but it is scanty and ill defined. A section through the ventral part shows it to consist of the following layers from without inward. (1) A layer of olfactory nerve-fibres, which are the non-medullated axones prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribiform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) Glomerular layer (stratum glomerulosum).—This contains numerous spheroidal reticulated enlargements, termed glomeruli, which are produced by the branching and arborization of the processes of the olfactory nerve-fibres with the descending dendrites of the mitral cells. (3) Molecular layer.—This layer is formed of a matrix of neuroglia, embedded in which are the mitral cells. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborizes as indicated above, and others which interlace with similar dendrites of neighboring mitral cells. The axones pass through the next layer into the white matter of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) Nerve-fibre layer.—This lies next the central core of neuroglia, and its fibres consist of the axones or afferent processes of the mitral cells which are passing to the brain; some efferent fibres are, however, also present, and terminate in the

molecular layer, but nothing is known as to their exact origin. It is to be remembered that the olfactory path is uncrossed or almost completely uncrossed.

The Gray Matter of the Ganglia or the Ganglionar Gray Matter.—These ganglia have been previously described. They are as follows: The corpus striatum, the optic thalamus, the external geniculate body, the internal geniculate body, the nucleus of Luys, the red nucleus of the tegmentum, the anterior quadrigeninal body, the posterior quadrigeninal body, the substantia nigra, and the interpeduncular ganglion.

The Central or Ventricular Gray Matter.—This includes the lamina cinerea, the tuber cinereum, the middle commissure, the nuclei of the third and fourth cranial nerves, and the gray matter about the aqueduct of Sylvius.

IV. The Hind-brain (Rhombencephalon).

From the hind-brain or rhombencephalon, as previously stated, come two vesicles, the metencephalon, or upper portion of the hind-brain or the hind-brain proper, and the myelencephalon, or lower portion of the hind-brain. From the metencephalon come the pons and the cerebellum. From the myelencephalon comes the medulla oblongata. The original hind-brain remains in the brain of the adult as the fourth ventricle.

Pons Varolii (Figs. 557, 599, and 603).—The pons Varolii is the bond of union between the various segments of the encephalon, connecting the cerebrum above, the medulla oblongata below, and the cerebellum behind. It lies upon a portion of the clivus, the groove of bone between the foramen magnum and the dorsum sellae, and is situated above the medulla oblongata, below the crura cerebri, and between the hemispheres of the cerebellum. It is about an inch in length, an inch in thickness, and an inch and a half in width. It presents four surfaces: the superior surface, which is attached, by direct continuation of fibres, to the mid-brain; the inferior surface, which is continuous with the medulla oblongata; the anterior or ventral and the posterior or dorsal surfaces are free.

The Anterior or Ventral Surface, the Tuber Annulare or Base (pars basilaris pontis), is very prominent, markedly convex from side to side, but less so from before backward. It consists of transverse white fibres (Fig. 594), which arch like a bridge across the middle line, and on either side are gathered together into a compact mass, forming the middle peduncle of the cerebellum (Fig. 599). Above and below it presents a well-defined border; below, its transverse fibres slightly overlap the pyramidal bodies of the medulla, which disappear into its substance; above, the transverse fibres slightly overlap the crura cerebri which emerge from it. This surface rests upon the clivus of the sphenoid bone, and presents in the middle line a longitudinal groove (sulcus basilaris) (Fig. 603), wider in front than behind, in which rests the basilar artery. Slightly in advance of the middle of the ventral surface of the pons and at the margin the two roots of the fifth nerve emerge.

The Posterior or Dorsal Surface (pars dorsalis pontis).—The posterior or dorsal surface of the pons is free, but is concealed from view by the cerebellum. It forms the upper part of the floor of the fourth ventricle, and will be described with this cavity (Fig. 604 and p. 942).

Structure.—Transverse sections of the pons Varolii show that it consists of two parts, which differ in appearance and structure from each other: the anterior or ventral portion (Fig. 594) consists for the most part of fibres arranged in transverse and longitudinal bundles with a small amount of gray matter; the posterior or dorsal portion is chiefly constituted by a continuation upward of the reticular formation of the gray matter of the medulla, and is called the tegmental portion, as most of its constituents are continued into the tegmentum of the crus cerebri. It is subdivided into lateral halves by a median raphé continuous with that of the
medulla, but the raphé does not extend into the ventral half of the pons, being here obliterated by the transverse fibres.

**Transverse Fibres of the Pons.**—The transverse fibres are placed in the ventral portion of the pons. These are disposed in three sets:

1. The **Superficial or Ventral Transverse Fibres** (*fibrae pontis superficiales*) (Fig. 594) constitute a rather thin layer on the ventral surface of the pons. This thin white layer is called the *tuber annulare*.

2. The **Middle or Deep Transverse Fibres** are placed dorsally or above the superficial transverse fibres, and form a thick layer, with much gray matter between them. These collections of gray matter are named the *nuclei pontis*. In this layer of transverse fibres are longitudinal fibres coming from the middle three-fifths of the crustae and passing to the pyramids of the medulla and also fibres of the fronto-pontal, intermediate, and temporo-frontal tracts (Santee). The *middle cerebellar peduncles* (*brachia pontis*) (Fig. 599) are formed by the superficial and middle transverse fibres.

3. The **Dorsal Transverse or Dorsal Deep Transverse Fibres** lie dorsally to the middle transverse fibres and the pyramidal fibres between them and the *formatio reticularis*. These fibres are collected into a distinct bundle which is most definite in the posterior portion of the pons and in which region it is named the *trapezium* (*corpus trapezoideum*), because of its shape. The trapezium is the mark of the boundary between the dorsal and ventral surfaces. The chief origin of the trapezium is from the cochlear nerve nuclei; they decussate and pass by the lateral fillet to the inferior quadrigeminal body. Santee points out that the trapezium and lateral fillet are part of the auditory conduction path.

**Longitudinal Fibres of the Pons.**—These are found in both the ventral and dorsal portions. There are three sets:
The Ventral Longitudinal or Ventral Deep Longitudinal Fibres (Fig. 594) are chiefly the continuation of the pyramidal fibres of the crista, which reach the pyramids of the medulla. They form a thick bundle. Among these fibres are some from the opposite cerebellar peduncles and the nuclei pontis. During the descent of the pyramidal tract it grows constantly smaller, because it loses here and there fibres which pass to motor cranial-nerve nuclei. The pressure of the thick bundle of pyramidal fibres causes a bulging of the superficial transverse fibres on the ventral surface of the pons and the formation of the mesial groove between them.

The Middle Longitudinal or Dorsal Deep Longitudinal Fibres are placed in the floor of the fourth ventricle in the pontine formatio reticularis, which is continuous with the formatio reticularis of the medulla oblongata. The pontine formatio reticularis is a network of these longitudinal fibres with some oblique fibres, the network containing gray matter. Some of the gray matter of the formatio reticularis forms the nuclei of certain cranial nerves; the rest of it forms the nuclei of the formatio reticularis. Santee describes six bundles of longitudinal fibres in the formatio reticularis: 1. The fillet (lemniscus), consisting of the lateral, the median, and the superior fillet (lemniscus lateralis,lemniscus medialis,lemniscus superior), passing to and through the tegmentum to the thalamus and the two quadrigeminal bodies. 2. The posterior longitudinal bundle (fasciculus longitudinalis medialis) contains both ascending and descending fibres; most of the fibres do not decussate but reach the anterior column of the same side of the cord. Some of its fibres decussate through the pons, medulla, and mid-brain. According to Santee, it receives ascending fibres from the gray matter of the anterior cornu of the spinal cord, from the sensory nuclei of cranial nerves, and through the middle peduncle from the cerebellum. It terminates in the subthalamic region. The fibres decussate across the posterior commissure. In this bundle are motor fibres passing from the sixth to the third nerves and from the third to the seventh. 3. The anterior longitudinal bundle (fasciculus ventralis) passes from the superior quadrigeminal body to the gray matter of the anterior cornu of the cervical cord. “It is the pupillo-dilator tract.”

4. The olivary bundle or the central tegmental tract (fasciculus tegmenti centralis) arises from the inferior olivary nucleus of the medulla, ascends to the lenticular nucleus, from which situation some of the fibres pass to the cortex. 5. The crossed descending tract from the red nucleus. It arises in the red nucleus of the tegmentum, soon crosses the raphé and, as Barker points out, reaches the lumbar region of the cord. In the pons the fibres are in the lateral fillet. 6. The ascending or inferior sensory root of the fifth nerve (tractus spinalis nervi trigemini) arises near the Rolandic tubercle in the medulla and effects a junction with the superior root ventrally to the superior peduncles of the cerebellum.

The Dorsal Longitudinal or Superficial Longitudinal Fibres constitute the roof of the superior portion of the fourth ventricle, and form the superior peduncles of the cerebellum (p. 932) and the valve of Vieussens (p. 933).

Gray Matter of the Pons.—The nuclei pontis constitute a portion of it, the gray matter of the formatio reticularis the balance.

The Nuclei Pontis, which have been previously referred to, are collections of gray matter on each side of the pons, between the fibres of the middle transverse bundle and of the ventral longitudinal bundle of the pons. The nucleus pontis of each side receives fibres from the crista—viz., the intermediate bundle, the frontal cerebro-cortico-pontal tract (p. 893), and the temporal cerebro-cortico-ponsal tract (p. 894), and also receives fibres from the middle peduncle of the cerebellum (p. 934). It sends fibres by the middle peduncle to the opposite cerebellar hemisphere. The nuclei pontis contain numerous multipolar ganglion cells.

1 Anatomy of the Brain and Spinal Cord. By Harris E. Santee.
The Gray Matter of the Pontine or Formatio Reticularis forms the superior olivary nucleus, the nuclei of the trapezium, numerous nuclei of the formatio reticularis, and nuclei of certain cranial nerves. The portion of the formatio reticularis between the roots of the sixth pair of cranial nerves is called the formatio reticularis alba; the portion between the roots of the sixth and seventh nerves is called the formatio reticularis grisea.

The Superior Olivary Nucleus (nucleus olivaris superior) is upon the dorsal surface of the outer part of that collection of fibres known as the trapezium. It is not large enough to be visible to the naked eye and contains very small nerve-cells. It is a part of the auditory pathway, and its fibres enter the accessory auditory nucleus of the opposite side. The nuclei of the trapezium are in the auditory pathway. There are numerous other nuclei in the formatio reticularis (nuclei of the formatio reticularis, or the nucleus magnocellularis diffusus of Koelliker). The cells of these nuclei are large and multipolar, and their axones cross to the opposite side of the pons. They receive fibres from cranial-nerve nuclei and axones from the cells of the folium of the cerebellum which are called cells of Purkinje. These nuclei are probably connected with various pontine tracts.

The Nuclei of the Fifth Nerve (Fig. 613) in the pons are two in number, one for the motor root and the other for the sensory. The motor nucleus is situated in the higher portion of the pons, close under the dorsal surface and along the line of the lateral margin of the fourth ventricle. The sensory nucleus lies external to the motor one, beneath the superior peduncle of the cerebellum, which forms the lateral boundary of the upper half of the fourth ventricle. Some of the fibres from these nuclei pass to the raphé of the pons, and thence probably to the higher parts of the brain; the rest form the nerve-roots of the motor and sensory parts of the fifth nerve respectively. They pass through the pons to emerge on its ventral surface at its lateral and constricted portion, nearer its superior than its inferior margin. It must be mentioned that the whole of the roots of the fifth nerve are not formed from these nuclei. The sensory root is partly formed by a long tract of fibres, known as the ascending root, which can be traced through the pons to the nucleus of Rolando in the medulla. The motor root, in like manner, is partly formed by a long tract of fibres, which passes downward from the gray matter in the floor of the fourth ventricle and the floor of the Sylvian aqueduct and which is termed the descending root.

The Nucleus of the Sixth Nerve (Fig. 613) is situated beneath the floor of the fourth ventricle, on either side of the middle line. It lies close to the root of the facial nerve, immediately to be described, being a little external to and beneath it, and corresponds to the upper half of the fasciculus teres of the floor of the fourth ventricle (Fig. 606). The fibres pass through the substance of the pons, and emerge at the lower margin of this structure, between it and the upper end of the medulla.

The Nucleus of the Facial Nerve (nucleus n. facialis) (Fig. 613) is of elongated form, and is situated deeply in the reticular formation below the superior fovea of the floor of the fourth ventricle. The roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backward and inward till they reach the floor of the fourth ventricle, close to the median groove, where they are collected into a rounded bundle. This passes upward and forward, producing an elevation (fasciculus teres) in the floor of the ventricle, and then takes a sharp bend and arches outward through the substance of the pons to emerge at its lower border in the interval between the olivary and restiform bodies of the medulla. The pars intermedia of Wrisberg takes origin from the floor of the fourth ventricle beneath the inferior fovea.

The Nuclei of the Auditory Nerve (nuclei n. acustici) (Fig. 613) are two in number, dorsal and ventral. The origin of the dorsal or vestibular root is from a nucleus situated in the medulla, but prolonged upward into the pons, where it lies beneath the
upper half of the floor of the fourth ventricle (nuclei n. vestibularis). The dorsal root also takes origin from the cerebellum (from the nucleus fastigii and the nucleus globose). According to Golgi, the vestibular root is also in connection with the nucleus of Deiters and the nucleus of Bechterew. The ventral or cochlear root arises from the ventral or accessory nucleus (nuclei n. cochlearis) which is also partly contained in the medulla and partly in the pons. In the medulla it is situated on the antero-external surface of the restiform body, lying between the vestibular and cochlear divisions of the auditory nerve, the latter being to its outer side. In the pons it is seen to lie beyond the boundary of the fourth ventricle on the outer and ventral aspect of the restiform body. A third nucleus, nucleus of Deiters, is sometimes termed the outer nucleus of the auditory nerve. It is situated below the outer angle of the fourth ventricle, and contains multipolar nerve-cells of large size. The outer portion of the nucleus of Deiters is called Bechterew's nucleus. The root of the auditory nerve consists of two portions, lateral and mesial, which pass, one to the outer and the other to the inner side of the restiform body, those from the lateral part arising mainly from the ventral nucleus, those from the mesial part arising from the dorsal auditory nucleus. They emerge at the lower border of the pons, in the groove between the olivary and restiform bodies.

The Cerebellum or Little Brain (Figs. 557, 595, 596, 597, 598, and 599).—The cerebellum is contained in the inferior occipital fossae, and is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium cerebelli. In form it is oblong and flattened from above downward, its great diameter being from side to side. It measures from three and a half to four inches transversely, two to two and a half inches from before backward, and is about two inches thick in the centre, and about six lines thick at the circumference. It consists of gray and white matter: the former, darker than that of the cerebrum, occupies the surface (substantia corticalis), and masses of it are also found in the interior. The white matter is in the interior (corpus medullare). The surface of the cerebellum is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminae of which it is composed.

Lobes of the Cerebellum.—The cerebellum consists of three parts or lobes, a median and two lateral. They are all continuous with each other, and are substantially the same in structure. The median portion is called the worm or vermi-form process (vermis), from the annulated appearance which it presents, owing to transverse ridges and furrows upon it. On the upper surface of the cerebellum, the worm is only slightly elevated above the level of the lateral portions, but on the under surface it is sunk almost out of sight in a deep depression, which is called the valley or vallecula (vallecula cerebelli). The lateral parts of the cerebellum are called hemispheres (hemisphaeria cerebelli); they attain a considerable size, overlapping and obscuring the inferior part of the worm. Below and behind they are separated by a deep notch, the posterior cerebellar notch or the incisura marsupialis (incisura cerebelli posterior), and in front by a broader, shallower notch, the anterior cerebellar notch or the incisura semilunaris (incisura cerebelli anterior). The anterior notch lies close to the pons and upper part of the medulla, and its upper edge encircles the posterior corpora quadrigemina. The posterior notch is free, and contains, in the recent state, the upper part of the falx cerebelli. The sides of the notches are formed by the margins of the hemispheres, while the bottom of the notches is formed by the anterior and posterior extremities of the worm respectively. The cerebellum is characterized by its laminated or foliated appearance; it is everywhere marked by deep, transverse, somewhat curved fissures, which lie close together, and extend for a considerable depth into the substance of the cerebellum, dividing it into a series of layers or leaves. Upon making sections across the laminae
it will be seen that the folia, though differing in appearance from the convolutions of the cerebrum, are homologous with them, inasmuch as they consist of a central white substance, with a covering or cortex of gray matter.

The largest and deepest fissure is the great horizontal fissure (sulcus horizontalis cerebelli) (Figs. 595 and 596). It commences in front at the pons, and passes horizontally around the free margin of the hemisphere to the middle line behind, and divides the cerebellum into an upper and lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual folia or laminae from each other.

When the cerebellum is removed from the pons and medulla, the transverse fissure (fissura transversa cerebelli) is seen upon its anterior margin. This fissure is between the superior and inferior medullary laminae.

The white matter in the interior of the cerebellum is known as the medullary body (corpus medullare). About the middle it divides into a superior and an inferior lamina (laminae medullares). These laminae help to form the fourth ventricle. The superior lamina is composed of the superior medullary velum and the peduncles of the cerebellum. The inferior lamina constitutes the inferior medullary velum.

The cerebellum is connected to the cerebrum, pons, and medulla by three pairs of peduncles, which will be described in the sequel; a superior pair connect it with the cerebrum; a middle pair, with the pons; and an inferior pair, with the medulla.

The Upper Surface of the Cerebellum (facies cerebelli superior) (Fig. 595).—The superior surface of the cerebellum is somewhat elevated in the middle line and sloped toward its circumference, its hemispheres being connected together by an elevated median portion or lobe, the superior vermis or superior vermis process (vermis superior cerebelli). The front of the superior vermis is elevated, and the highest point is called the monticulus cerebelli. The surface is traversed by four curved fissures, which are named from their situation, in front or behind two prominent lobes of the worm, the central lobe and the clivus: (1) the pre-central fissure (sulcus praecentralis cerebelli); (2) the post-central fissure (sulcus postcentralis); (3) the pre-clival fissure, and (4) the post-clival fissure. These four fissures divide the entire upper surface of the cerebellum into five lobes, but the portion of the lobe in the worm has received a different name from that in the hemisphere, though the two are continuous with each other. The five lobes in the worm are named from before backward: (1) the lingula, (2) the central lobule, (3) the culmen monticuli, (4) the clivus monticuli, and (5) the folium cacuminis (folium vermis).
The five lobes in the hemispheres are named from before backward: (1) the *fraenulum*, (2) the *ala lobuli centralis*, (3) *anterior crescentic*, (4) *posterior crescentic*, and (5) *posterior superior*. The arrangement of these fissures and lobules will be understood by reference to the accompanying schematic arrangement, in which the lobules are named in order from before backward with the fissures which separate them:

**Worm.**

- Lingula.

**Hemisphere.**

- Fraenulum.

**Pre-central Fissure.**

- Lobulus centralis.

- Ala lobuli centralis.

**Post-central Fissure.**

- Culmen monticuli.

- Anterior crescentic lobe.

**Pre-clival Fissure.**

- Clivus monticuli.

- Posterior crescentic lobe.

**Post-clival Fissure.**

- Folium cacuminis.

- Posterior superior lobe.

The *Lingula* (*lingula cerebelli*) (Fig. 508) is a tongue-shaped process of the vermis, which lies in the anterior cerebellar notch in front of the lobulus centralis, and is partially or completely concealed by it. It is in relation, in front, with the valve of Vieuxsens, on the dorsal surface of which it rests and with which it is connected; its white matter being continuous with that of the valve. At either side the lingula gradually shades off, and is prolonged only for a short distance into the hemispheres, where it forms the *fraenulum* (*vinculum lingualae cerebelli*). This does not stretch beyond the superior peduncle of the cerebellum over which it lies.

The **Central Lobe and Alae** (*lobulus centralis*).—The lobus or lobulus centralis is a small square lobe, situated in the anterior notch. It overlaps the lingula and is in turn partially concealed by the culmen monticuli. Laterally the lobulus centralis extends along the upper and anterior part of each hemisphere, where it forms a wing-like prolongation, the *ala lobuli centralis*.

The **Culmen Monticuli Cerebelli** is much larger than the two lobes just described, and constitutes, with the succeeding lobe, the *clivus*, the bulk of the upper worm. In front it partially overlaps and obscures the lobulus centralis, and behind it is separated from the clivus by the *pre-clival fissure*. It forms the most prominent part of the upper worm, and is marked on its surface by three or four secondary fissures, dividing it up into smaller lobules. Laterally it is continuous with the *anterior crescentic lobe of the hemisphere* (*pars anterior lobuli quadrangularis*), which is distinctly differentiated from the posterior crescentic lobe by the pre-clival fissure, though the two were formerly classed together as the quadrate lobe of the lateral hemisphere.

The **Clivus Monticuli** (*declive monticuli cerebelli*) is of considerable size, and, as stated above, forms with the culmen the major part of the superior worm. It consists of a group of laminae, which in front are separated from the culmen by the pre-clival fissure and behind appear to be almost continuous with the folium cacuminis, especially in the median line; but it will be found, on careful examination, to be separated from it by a well-defined fissure, the *post-clival fissure*. Laterally this lobe is continued into the hemispheres as the *posterior crescentic lobe* (*pars posterior lobuli quadrangularis*), which is somewhat semilunar in shape, and, with the anterior crescentic lobe, constitutes the greater part of the upper surface of the hemispheres.
The Folium Cacuminis (folium vermis) is a short and narrow, concealed band at the posterior extremity of the worm, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally it expands in either hemisphere into a considerable lobe, which is semilunar in shape, and is situated at the postero-superior part of the hemisphere and is bounded below by the great horizontal fissure. It is named the posterior superior lobe (lobulus semilunaris superior), and occupies the posterior third of the upper surface of the hemisphere, forming its rounded postero-lateral border.

The Under Surface of the Cerebellum (facies cerebelli inferior) (Figs. 596 and 597). —The under surface of the cerebellum presents in the middle line the inferior vermis severeform process (vermis inferior cerebelli), buried in the vallecula, and separated from the hemispheres by lateral grooves. Here, as on the upper surface, there are deep fissures, dividing it into separate segments or lobes, but the arrangement is more complicated, and the relation of the segments of the worm to those of the hemisphere is less clearly marked. The fissures are three
in number, but are not so regularly disposed as those on the upper surface (Fig. 597). They are named, from their relation to the pyramid and nodule, two of the lobes on the under surface of the worm: (1) post-nodular, (2) pre-pyramidal, and (3) post-pyramidal fissures. The part of the worm in front of the post-nodular fissure is termed the nodule (nodulus vermis), and the lobule in the hemisphere corresponding with this is the flocculus. The next lobe is situated between the post-nodular and pre-pyramidal fissures. In the vermiform process it is known as the uvula, and its lateral expansion in the hemisphere is named the amygdala or tonsil. The lobule of the worm between the pre- and post-pyramidal fissures is the pyramid, and its corresponding part in the hemisphere is the biventral or digastric lobe. Finally, behind the post-pyramidal fissure in the worm is a small lobe, the tuber valvulae or tuber posticum; this, in the hemispheres, expands into a large lobe, which occupies at least two-thirds of the inferior surface of the cerebellum, and is subdivided into two by a secondary fissure, named the post-gracile fissure. The anterior of the two subdivisions is named the slender lobe; and the posterior, the inferior semilunar or posterior inferior lobe. These fissures and lobes are here arranged, from before backward, in a schematic form:

The Fissures of the Under Surfaces of the Cerebellum.—The chief fissures of the under surface, as stated above, are three in number, and are not so regularly disposed as on the upper surface.

(1) The Post-nodular Fissure in the worm courses transversely across it, separating the nodule in front from the uvula behind. When it reaches the hemispheres it passes in front of the amygdala, and then crosses between the flocculus in front and the biventral lobe behind, and joins the anterior end of the great horizontal fissure.

(2) The Pre-pyramidal Fissure crosses the worm between the uvula in front and the pyramid behind, then curves laterally behind the amygdala, and passes forward along the outer border of this lobe, between it and the biventral lobe, to join the post-nodular sulcus.

(3) The Post-pyramidal Fissure passes across the worm behind the pyramid and in front of the tuber valvulae, and in the hemispheres courses behind the amygdala and biventral lobes, and then along the outer border of the biventral lobe to the post-nodular sulcus. It cuts off at least two-thirds of the inferior surface of the hemisphere. From it a secondary sulcus springs, and, coursing forward and outward, divides this surface into two parts and falls into the great horizontal fissure. This sulcus is termed the post-gracile fissure.

The Lobes of the Inferior Surface of the Cerebellum.—The Nodule (nodulus vermis) is a distinct prominence, forming the anterior extremity of the inferior worm. It projects into the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla andpons. On each side of
the nodule is a thin layer of white substance, named the inferior medullary velum. It is semilunar in form, its convex border being continuous with the middle peduncle of the cerebellum; it extends on either side as far as the flocculus, which it connects with the nodule.

The flocculus (flocculi secondarii) is a prominent, irregular lobule, situated just in front of the biventral lobe, between it and the middle peduncle of the cerebellum. It takes origin from a fold of gray matter in the inferior medullary velum, which is anterior to the tonsil. This fold is called the peduncle of the flocculus (pedunculus flocculi). Externally the gray fold enlarges and the enlargement is the flocculus. It is subdivided into a few small laminae.

The Uvula (uvula vermis) occupies a considerable portion of the inferior worm; it is separated on either side from the amygdala by a deep groove, the sulcus valleculae, at the bottom of which it is connected to the amygdala by a commissure of gray matter, indented on its surface, and called the furrowed band. The uvula is marked on its surface by three or four transverse fissures.

The Tonsil or Amygdala (tonsilla cerebelli) is a rounded mass in the lateral hemisphere. There are two tonsils, one in each lateral hemisphere. Each lies in a deep fossa between the uvula and the biventral lobe; this fossa is known by the name of the bird's nest (nidus avis).

The Pyramid Lobe (pyramis vermis) is a conical projection, forming the largest prominence of the lower worm. It is separated from the hemispheres by the sulcus valleculae, across which it is connected to the biventral lobe by an indistinct band of gray matter, analogous to the furrowed band already described.

The Biventral Lobe or Digastric Lobule (lobulus biventer) is triangular in shape, with the apex pointing inward and backward to become joined by the connecting band to the pyramid. The external border is separated from the slender lobe by the post-pyramidal fissure. The base is directed forward, and is on a line with the anterior border of the amygdala, and is separated from the flocculus by the post-nodular fissure.

The Tuber Valvulae or Tuber Posticum (tuber vermis) is the posterior division of the inferior worm. It is of small size, and laterally spreads out into the large posterior inferior lobes of the hemispheres. These lobes, which, as stated above, comprise at least two-thirds of the inferior surface of the hemisphere, are divided into two by the post-gracile fissure. The anterior lobe is named the slender lobe, and the posterior, the inferior semilunar lobe (lobulus semilunaris inferior). Both these lobes show a tendency to subdivision into two; that of the slender lobe is well marked, and its subdivisions are sometimes described as distinct lobes and named the anterior and posterior slender lobes, the fissure between them being termed the intra-gracile fissure.

The Internal Structure of the Cerebellum.—The cerebellum consists of white and gray matter.

The White Matter.—If a sagittal section (Fig. 598) is made through either hemisphere of the cerebellum, the interior will be found to consist of a central stem of white matter, the medullary body (corpus medullare), which contains in its interior a gray mass, the corpus dentatum (nucleus dentatus). It is a fold of gray matter thrown into corrugations and surrounding a centre of white matter. From the surface of this central stem a series of plates of medullary matter are detached, which, covered with gray matter, form the laminae. In consequence of the main branches from the central stem dividing and subdividing, the section presents a characteristic appearance, which is named the arbor vitae cerebelli. If a vertical section is made in the median plane of the cerebellum it will be found that the central stem divides into two main branches, which, from their direction, may be named respectively the vertical and the horizontal branch. The vertical branch passes upward to the culmen, where it subdivides freely, some of its ramifi-
cations passing forward and upward to the central lobe. The horizontal branch passes backward to the folium caecuminis, considerably diminished in size in consequence of having given off large secondary branches: one, from its upper surface, ascends to the clivus; the others descend, and enter the lobes in the inferior vermis process, the tuber valvulae, the pyramid, the uvula, and the nodule. In the interior of the worm is white matter called the corpus trapezoides. It is not necessary to describe in detail the various divisions of the white matter, as they correspond to the lobes on the surface.

The white matter of the cerebellum includes three systems of fibres: (1) projection or peduncular fibres, which are directly continuous with those of the peduncles of the cerebellum; (2) the fibres proper (fibrae propriae) of the cerebellum itself.

**Projection or Peduncular Fibres.**—The medullary body, as it emerges from the anterior cerebellar notch, is composed of projection fibres. These fibres are continuous with the branches of the medullary body and constitute the arbor vitae. The medullary body divides into a superior lamina and an inferior lamina, and it also forms a portion of the fourth ventricle. The inferior lamina is the inferior medullary velum, and its fibres reach the nodule and each flocculus. The superior lamina forms the superior medullary velum and the cerebellar peduncles.

**The Peduncles of the Cerebellum** (Figs. 599 and 600).—From the anterior part of each hemisphere arise three large processes or peduncles—superior, middle, and inferior peduncles—by which the cerebellum is connected with the rest of the encephalon.

The Superior Cerebellar Peduncles or Crura ad Cerebrum (brachia conjunctiva cerebelli) form the upper lateral boundaries of the floor of the fourth ventricle. As they extend forward and upward they converge on the dorsal aspect of the ventricle, and thus assist in roofing it in. They may be traced as far as the corpora quadrigemina, under which they pass. They enter the upper and mesial part of
the medullary substance of the hemispheres, beneath the ala lobuli centralis and the fraenulum, and pass to a great extent into the interior of the corpus dentatum, though some of their fibres wind around it and reach the gray cortical matter, especially of the inferior surface.

There are both afferent and efferent fibres in the superior peduncle, and the fibres are in two bundles (Fig. 600). The fibres to the cerebrum are axones of cells, most of which are situated in the corpus dentatum, but some of the fibres to the cerebrum come from the Purkinje cells of the cerebellar cortex, and probably also a few come from the smaller nuclei in the central white substance. The majority of the fibres decussate below the corpora quadrigemina, and pass to the opposite red nucleus of the tegmentum, from which a relay is prolonged through the optic thalamus to the cerebral cortex. The fibres of the second group take origin in the opposite red nucleus and end in the corpus dentatum (Santee).

**Fig. 599.**—The peduncles of the cerebellum. On the left the three peduncles have been cut at their entrance into the cerebellum; on the right side they are shown penetrating the cerebellar hemisphere. (Poirier and Charpy.)

**The Valve of Vieuusens or Superior Medullary Velum (velum medullare anterius) (Figs. 574, 584, 604, and 606).**—Stretched across from one superior cerebellar peduncle to the other is a thin, transparent lamina of white matter, the valve of Vieuusens; on to the dorsal surface of its lower half the folia of the lingula are prolonged. It helps to form with the superior peduncles the roof of the upper part of the fourth ventricle, and is continuous with the central white stem of the cerebellum. It is narrow above, where it passes beneath the corpora quadrigemina, and broader below, at its connection with the white substance of the superior worm of the cerebellum. A slightly elevated ridge descends upon the upper part of the valve from between the lower corpora quadrigemina, and on either side of this may be seen the fourth nerve. The majority of the fibres of the superior medullary velum are chiefly longitudinal fibres, passing between the cerebrum and the worm of the cerebellum. What is known as the antero-lateral ascending cerebellar tract of Gowers is said by Hoche to pass to the worm by way of
the superior velum. The velum also contains some commissural fibres and decussating fibres of the roots of the fourth nerves.

The **Middle Peduncles** or **Crura ad Posterior** (*brachia pontis*) are the largest of the three pairs. They consist of a mass of curved fibres, which, as already described, pass to the pons and fovea, comprises most of the transverse fibres of the pons. These tracts are both afferent and efferent, and the middle peduncle emerges from the cerebellum at the anterior notch, between the margins of the great horizontal fissure. The fibres of the middle peduncle (Fig. 600) rise from all portions of the cortex of the cerebellum. In the peduncle the fibres effect a crossing, so that fibres from the anterior part of the hemisphere pass to the posterior part of the pons, and fibres from the posterior portion of the hemisphere pass to the anterior portion of the pons. The fibres approach the median line and terminate on both sides of the raphé in the nuclei pontis and the nuclei of the formatio reticularis (Cajal). The balance of the fibres are "axoncs of cell-bodies, situated mainly in the opposite nucleus pontis."¹ These fibres "form a segment in the indirect motor paths contained above the pons; in the medial

and lateral fifths, and the intermediate bundle of the crusta. Collaterals from both groups of fibres ascend and descend in the pons. They run upward with both crustae, but chiefly with the opposite one; and they accompany the fillet and posterior longitudinal bundle of the same side to the nuclei of the third, fourth, and sixth cranial nerves."

The **Intermediate Peduncles or Crura ad Medullam** (*corpora restiformia*) connect the cerebellum with the medulla oblongata. The fibres (Fig. 600) are both afferent and efferent and begin in the gray cortex of the upper surface of the cerebellar hemispheres and the worm. They descend in a direction downward and inward, from part of the lateral walls of the fourth ventricle, reach the medulla, and become the *restiform bodies*, which will be subsequently described (p. 941). The following are the chief sets of fibres in the inferior peduncles: 1. The **direct cerebellar tract**, which takes origin in Clarke's column of the spinal cord and terminates in the superior worm of the cerebellum. 2. The **external arciform fibres**, which rise in the grucile and cuneate nuclei of the medulla and terminate in the vermis superior. The posterior or uncrossed fibres terminate on the same side, the anterior or crossed fibres on the opposite side. 3. The **acustico-cerebellar tract**. These fibres originate from the nucleus of the auditory nerve in the floor of the fourth ventricle, and terminate in the opposite nucleus fastigii and nucleus globosus of the cerebellum. 4. Fibres which pass between the **lateral nucleus of the medulla oblongata** and the corresponding side of the cerebellar cortex. 5. The

***The Hind-Brain***

The descending cerebellar tract, which originates in the cerebellar cortex and which passes down by way of the restiform body of the medulla and the antero-lateral column of the spinal cord and reaches the anterior gray horn of the cord. 6. The internal arciform fibres, which pass between the cerebellar cortex and the opposite olivary body of the medulla (the cerebello-olivary tract). Santee emphasizes the fact that most of the fibres which emerge from the cerebellum in the middle and inferior peduncles are "axones of Purkinje's cells; they connect the cerebellum with the motor nuclei of cranial and spinal nerves."²

² Ibid.
The Fibres Proper of the Cerebellum.—The fibrae propriae of the cerebellum are of two kinds: (1) commissural fibres, which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part and others at the posterior part of the vermiciform process; (2) association fibres, which are antero-posterior fibres connecting adjacent laminae with each other.

The Gray Matter of the Cerebellum.—The gray matter of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

1. The Cortex of the Cerebellum (substantia corticalis) presents a characteristic foliated appearance, due to the series of laminae which are given off from the central white matter; these in their turn give off secondary laminae, which are covered with gray matter. This arrangement gives to the cut surface of the organ a foliated appearance (Fig. 598). Externally, the cortex is covered by pia matter; internally, is the medullary centre, consisting mainly of nerve-fibres.

Microscopic Appearance of the Cortex (Figs. 601 and 602).—The cortex presents a remarkable structure, consisting of two distinct layers—viz., an external or superficial molecular layer, and an internal, deep, nuclear, rust-colored, or granular layer. Between the two layers is an incomplete stratum of the characteristic cells of the cerebellum, the corpuscles of Purkinje.

The external, superficial gray or molecular layer (Figs. 601 and 602) consists of fibres and cells. The nerve-fibres are delicate fibrillae, and are derived from the following sources: (a) the dendrites and axone collaterals of Purkinje's cells; (b) fibres from cells in the granular layer; (c) fibres from the central white substance of the cerebellum; (d) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction. These are the processes of large glia-cells, situated in the granular layer. They pass outward to the periphery of the gray matter, where they expand into little conical enlargements, which form a sort of limiting membrane beneath the pia mater, analogous to the membrana limitans interna in the retina, formed by the fibres of Müller.

The cells of the molecular layer are small, and are arranged in two strata, an outer and an inner. They all possess branching axis-cylinder processes; those of the inner layer run for some distance horizontally, i.e., parallel with the surface of the folia, giving off at intervals collaterals, which pass in a vertical direction toward the cell-bodies of Purkinje's corpuscles, around which they become enlarged and ramify like a basket. Hence these cells of the inner portion of the external layer are named basket-cells (Fig. 601).

The cells or corpuscles of Purkinje (Fig. 602) are flask-shaped cells, situated at the junction of the molecular and granular layers, their bases resting against the latter. From the bottom of each flask one axis-cylinder process arises; this passes through the granular layer, and, becoming medullated, is continued as a nerve-fibre in the medullary substance beneath. This axone gives off fine collaterals as it passes through the granular layer, some of which run back into the molecular layer. From the neck of the flask numerous dendrites are given off, which branch in an antler-like manner in the molecular layer and terminate in free extremities.

The internal, rust-colored, nuclear or granular layer (Figs. 601 and 602) is characterized by containing numerous small nerve-cells or granules of a reddish-brown color, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with short dendrites, which spread out in a spider-like manner in the granular layer. Their axones pass outward into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are also to be observed some larger cells, of the type termed Golgi cells (Fig. 601). Their axones undergo frequent division as soon as they leave the nerve-cells, and pass into the granular layer, while their dendrites ramify chiefly in the molecular layer.
Finally, in the gray matter of the cerebellar cortex fibres are to be seen which come from the white centre and penetrate the cortex. The cell origin of these fibres is unknown, though it is believed that it is probably in the gray matter of the spinal cord. Some of these fibres end in the granular layer, by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the moss fibres (Fig. 601); they form an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells, and hence they have been named the clinging or tendril fibres (Fig. 601).
superior cerebellar peduncle emerge. The **nucleus emboliformis** is a mass of gray matter placed immediately to the inner side of the corpus dentatum, and partly covering its hilum. The **nucleus globosus** is an elongated mass of gray matter, directed antero-posteriorly, and placed to the inner side of the preceding. The **nucleus fastigii** is somewhat larger than the other two, and is situated close to the middle line at the anterior end of the superior vermiiform process, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white matter. It is known as the **roof nucleus of Stilling**.

**Weight of the Cerebellum.**—Its average weight in the male is about 5 oz., 4 drs. It attains its maximum weight between the twenty-fifth and fortieth years, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to $8\frac{1}{2}$, and in the female as 1 to 8. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13, and 1 to 26; by Cruveilhier, the proportion was found to be 1 to 20.

V. The Medulla Oblongata (Myelencephalon) (Figs. 557, 594, 603, 604).

The medulla oblongata, known also as the **spinal bulb**, is the lowest division of the encephalon, and is continuous with the spinal cord. It is, in fact, the intracranial portion of the spinal cord. It is developed from the fifth cerebral vesicle, the cavity of which forms the lower half of the fourth ventricle. It extends from the lower margin of the pons Varolii to a plane passing transversely just below the decussation of the pyramids, at which level the spinal cord commences. This plane corresponds to the lower margin of the foramen magnum. The upper limit of the medulla is marked off from the pons Varolii on its ventral aspect by the abrupt lower margin of the latter.

The medulla oblongata is directed from above obliquely downward and backward; its ventral surface rests on the basilar groove of the occipital bone, while its dorsal surface is received into the fossa between the hemispheres of the cerebellum, and forms the lower part of the floor of the fourth ventricle. It is pyramidal in shape, its broad extremity directed upward, its lower end being narrow at its point of connection with the cord. It measures an inch in length, three-quarters of an inch in breadth at its widest part, and half an inch in thickness. Its surface is marked, in the median line, in front and behind, by an **anterior** and a **posterior median fissure** (**fissura mediana anterior** and **fissura mediana posterior**), which are continuous with similar fissures on the anterior and posterior surfaces of the cord, but neither one of them extends the entire length of the bulb. The anterior fissure contains a fold of pia mater, and terminates just below the pons in a **cul-de-sac**, the **foramen caecum of Vicq d’Azyr**. It is interrupted at its lower part by some bundles of fibres, which cross obliquely from one side to the other, forming the **decussation of the pyramids** (**decussatio pyramidum**) (Figs. 594 and 605). The posterior fissure is a deep but narrow fissure, continued upward to about the middle of the medulla. As it ascends its depth diminishes, and about the middle of the posterior surface of the medulla the central canal of the cord
opens, and the lips of the shallow posterior fissure diverge and bound the triangular opening, which is the lower portion of the floor of the fourth ventricle (Figs. 604 and 606). As the lower half of the medulla contains the central canal of the cord, it is called the **closed portion**; the upper half of the medulla is above the opening of the central canal and is called the **open portion**.

These two fissures divide the medulla into two symmetrical halves, each half presenting elongated eminences, which are continuous with the columns of the cord. By taking the lines along which some of the cranial nerves emerge from the medulla as landmarks, the surface of this portion of the nervous system may be divided into three columns, in the same way as the spinal cord is divided into three columns by the lines corresponding to the points of exit of the anterior and posterior roots of the spinal nerves. The **hypoglossal nerve-roots** arise from a furrow on the antero-lateral surface of the medulla, which is known as the **antero-lateral furrow**, or the **ventro-lateral groove** (**sulcus lateralis anterior**). There is no furrow on the cord corresponding with this medullary furrow. The roots of the *glossopharyngeal* and *pneumogastric* nerves and the **accessory root of the spinal accessory nerve** lie in a furrow upon the postero-lateral surface of the medulla. This furrow is called the **postero-lateral furrow** or **dorso-lateral groove** (**sulcus lateralis posterior**). This groove is the continuation of the postero-lateral fissure of the cord. It is not straight, but turns forward as it ascends. At the termination of this groove anterio- rily the **seventh** and **eighth cranial nerves emerge**. At the lower portion of the medulla the groove ceases for a short distance as the direct cerebellar tract passes from the lateral to the posterior surface of the bulb. The **antero-column** comprises that portion which is situated between the anterior median fissure and the antero-lateral furrow; this column is called the **anterior pyramid** or simply the **pyramid** (Fig. 603). The **lateral column** comprises that portion which is situated between the antero-lateral and the postero-lateral furrows. In the lower part of the medulla this column is single, and is called the **lateral tract**; but in the upper part an oval-shaped body comes forward between it and the pyramid, and pushes aside the lateral tract. This is called the **olivary body** (Fig. 603). The **posterior column** (Fig. 604) comprises that portion which is situated between the postero-lateral furrow and the posterior median fissure. It is marked by slight furrows dividing it into smaller columns, and these in the lower part of the medulla are named, from without inward, the **fasciculus of Rolando**, the **fasciculus cuneatus** and the **fasciculus gracilis**; in the upper part of the medulla, the fasciculus of Rolando and the fasciculus cuneatus appear to become fused together and seem to form the single body, called the **restiform body** (Fig. 604). As a matter of fact the restiform body is not so formed (p. 941).

**The Pyramid** (**pyramis medullae oblongatae**) (Figs. 594 and 603).—The pyramid is a pyramidal bundle of white matter. A pyramid is placed one on either side of the anterior median fissure, and separated from the olivary body by a slight depression, from which the roots of the hypoglossal nerve emerge (antero-lateral furrow). At the lower border of the pons these bodies are somewhat constricted and are here crossed by a band of arched fibres, the **ponticulus of Arnold**; below this they become enlarged, and then taper as they descend to their lower extremity. The fibres of which compose these pyramids may be arranged in two bundles: an **outer**, continuous below with the **direct** or **uncrossed pyramidal tract** of the anterior column of the same side of the spinal cord, and an **inner**, continuous with the **crossed pyramidal tract** of the lateral column of the opposite side of the cord (Fig. 605). As will be subsequently mentioned, the direct pyramidal tract in the cord lies next to the anterior median fissure, but as the crossed pyramidal tract of the cord ascends to the medulla it decussates with its fellow of the opposite side across the anterior median fissure, and so displaces laterally the direct pyramidal tract, and ascends,
after decussation, through the medulla to its inner or mesial side. This decussation is usually spoken of as the **decussation of the pyramids** (Figs. 594 and 605), but it must be borne in mind that it is only a portion of the fibres of the pyramid (90 per cent. of them) which decussate; namely, those derived from the crossed pyramidal tract of the cord; the outermost fibres, derived from the anterior column of the cord, do not decussate. Each pyramid enters the substance of the pons in one bundle, and may be traced through it, after breaking up into several smaller fasciculi, into the corresponding crus cerebri.

The **Lateral Column or Lateral Area**.—The lateral column or area is between the antero-lateral and postero-lateral furrows. In the lower part of the medulla it is of the same width as the lateral column of the cord, and appears on the surface to be a direct continuation of it. As a matter of fact it is only a part of the lateral column of the spinal cord which is continued upward into this column; for the crossed pyramidal tract passes into the pyramid of the opposite side, and the direct cerebellar tract of the lateral column of the cord passes into the restiform body. The rest of the lateral column of the cord, that is to say, the **antero-lateral ground bundle** (*fasciculus proprius anterolateralis*) and the **antero-lateral cerebellar tract** (*fasciculus anterolateralis superficialis*), can be traced
upward into this area. In the upper part of the medulla, the lateral tract, on account of the interpolation of the olivary body, becomes almost concealed by this body.

The Olive, Olivary Body or Olivary Eminence (oliva) (Figs. 586, 589, and 603).—The olivary body or eminence is a prominent oval mass, bulging from the upper part of the lateral column of the medulla. It is situated on the outer side of the pyramid, from which it is separated by the slight groove, along which the fibres of the hypoglossal nerve emerge. It is separated externally from the restiform body by a longitudinal, narrow band of fibres, prolonged upward from the lateral tract, and by the groove, from which the glossopharyngeal, pneumogastric, and spinal accessory nerves arise. It is equal in breadth to the pyramid; it is broader above than below, and is about half an inch in length, being separated above from the pons Varolii by a slight depression, in which a band of arched fibres is sometimes to be seen. Numerous white fibres, superficial or external arciform or arcuate fibres (Fig. 607), are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body. The olivary body is formed by the olivary nucleus of the medulla (Fig. 607), a lamina of gray matter, the surface of which is covered by a very thin layer of white matter.

The Funiculus or Fasciculus of Rolando (fasciculus lateralis) (Fig. 604).—The fasciculus of Rolando is a longitudinal prominence on the outer side of the lateral tract. It begins at the lower end of the medulla by a tapering extremity, and has, apparently, no corresponding column in the cord. It gradually enlarges as it ascends, and forms, at a level with the lower border of the olivary body, a considerable prominence, known as the tubercle of Rolando (tuberculum Rolandi) (Fig. 607). This is caused by the substantia gelatinosa of Rolando of the cord gradually finding its way to the surface, so as to form a prominence there. About half an inch below the pons the fasciculus of Rolando appears to blend with the fasciculus cuneatus. In front, it is separated from the lateral tract by a distinct groove, the continuation upward of the postero-lateral groove of the cord; behind, the separation from the fasciculus cuneatus is much less distinct.

The Wedge-shaped or Cuneate Funiculus or the Fasciculus Cuneatus (Fig. 604) is the direct continuation upward of the postero-lateral column (tract of Burdach) of the cord. It is situated between the fasciculus of Rolando and the fasciculus gracilis. It enlarges as it ascends, and forms, opposite the lower extremity of the fourth ventricle, a slight eminence or enlargement, the cuneate tubercle (tuberculum cuneatum) (Fig. 604), which is marked only in children. Above this point it disappears from the surface.

The Slender Funiculus or the Fasciculus Gracilis (Fig. 604) is the direct continuation upward of the postero-median column of the cord (tract of Goll). It is a narrow white band, placed parallel to and along the side of the posterior median fissure. It is separated from the fasciculus cuneatus by a slight groove, continuous with that on the surface of the cord, which marks off the postero-median column. At first the fasciculi of the two sides lie in close contact on either side of the posterior median fissure. Opposite the apex of the fourth ventricle each presents an enlargement, the clava (Fig. 604); they then diverge and form the lateral boundaries of the lower part of the fourth ventricle, and gradually tapering off become no longer traceable. The surface prominence of the fasciculus gracilis is formed by the gray nucleus beneath. This nucleus is known as the nucleus fasciculi gracilis.

The Restiform Body (corpus restiforme) (Fig. 604).—The upper part of the posterior area of the medulla is occupied by the restiform body. It appears, at first sight, as if this body were the direct continuation upward of the fasciculus cuneatus and the fasciculus of Rolando, and it was formerly
described as such. This, however, is not so, for the restiform body is largely formed by a set of fibres, the superficial or external arciform or arcuate fibres (Fig. 607), which issue from the anterior median fissure and will presently be described. They pass laterally over the pyramid and olive, and assist in forming the restiform body. There is also a narrow strand of fibres, derived from the lateral column of the cord, the direct cerebellar tract (fasciculus cerebello-spinalis), which joins the above-mentioned arcuate fibres. These two sets of fibres, reinforced by the internal arcuate fibres from the opposite side of the medulla, form the restiform body.

The restiform bodies are the largest prominences of the medulla, and are placed between the lateral tracts in front and the fasciculus cuneatus behind, from both of which they are separated by slight grooves. As they ascend they diverge from each other, assist in forming the lower part of the lateral boundaries of the fourth ventricle, and then enter the corresponding hemisphere of the cerebellum, forming its inferior peduncles.

The Posterior Surface of the Medulla Oblongata (facies posterius) (Fig. 604).—The posterior surface of the medulla oblongata forms part of the floor of the fourth ventricle (Fig. 606). This portion is of a triangular form, bounded on each side by the diverging fasciculi graciles and cuneati and restiform bodies. The divergence of these two fasciculi and of the restiform bodies, together with the opening out of the posterior fissure and central canal of the spinal cord, displays in the floor of the ventricle the gray matter of the medulla, which is continuous below with the gray matter of the cord. In the middle line is seen a longitudinal furrow, which divides this part of the ventricle into right and left halves, and is continuous below with the central canal of the cord.

The Arciform or Arcuate Fibres (Fig. 607).—The arciform or arcuate fibres, which have been mentioned as forming part of the restiform body, are found in the upper half of the medulla, crossing its surface and also traversing its substance. They are divided for purposes of description into two sets—external and internal. The external or superficial arciform or arcuate fibres (fibrae arcuatae externae) have already been alluded to as crossing the pyramid and olivary body on each side. They emerge from the anterior median fissure, and if traced into it are found to enter the raphé and cross to the opposite side, after which their further course is a matter of some doubt. After emerging from the anterior median fissure they cross the pyramid and olivary body, often concealing from view the upper part of the cuneate and Rolandic fasciculi, and enter the restiform body. As they cross the olivary body they are reinforced by some of the internal arciform fibres, which come to the surface on the inner side of, or through, this structure. The internal arciform or arcuate fibres (fibrae arcuatae internae) are described with the microscopic anatomy of the medulla.

It is advisable, at this stage, to take up the consideration of the cavity of the fourth ventricle, an acquaintance with which will render the description of the internal structure of the medulla oblongata more intelligible.

The Fourth Ventricle (Ventriculus Quartus) (Fig. 606).
sides of the upper triangle are formed by the convergence of the superior peduncles of the cerebellum. These peduncles are separated below by a somewhat wide interval, but as they pass upward and forward toward the corpora quadrigemina they gradually converge and ultimately come into contact with each other. This cavity is therefore bounded laterally on each side by the superior peduncle of the cerebellum in its upper half, and by the fasciculus gracilis, the fasciculus cuneatus, and the restiform body in its lower half. It presents four angles. The upper angle reaches as high as the upper border of thepons, and corresponds with the lower opening of the aqueduct of Sylvius, by which this ventricle communicates with the third ventricle (Fig. 587). The lower angle is on a level with the lower border of the olivary body, and is continuous with the central canal of the spinal cord. From the resemblance that it bears to the point of a writing pen it has been named the calamus scriptorius. Its lateral angles extend for some distance between the medulla and the cerebellum, each forming a pointed lateral recess.

The Roof or Posterior Wall of the Fourth Ventricle.—The roof of the fourth ventricle is formed from above downward by the following structures: a part of the superior peduncles of the cerebellum, the anterior or superior medullary velum, the posterior or inferior medullary velum, the tela chorioides inferior, the obex, and the lingula. The superior half of the roof meets the inferior half at an acute angle to form the tent of the fourth ventricle (fastigium).

The Superior Peduncles of the Cerebellum (brachia conjunctiva cerebelli) (Figs. 557, 598, 599, 604, and 606).—The superior peduncles of the cerebellum, when they emerge from the medullary substance of its hemispheres, pass upward and forward, forming the lateral boundaries of the upper half of the fourth ventricle, but, converging as they approach the corpora quadrigemina, the mesial portions of the peduncles form a part of the roof of the cavity, in consequence of the ventricle extending to a slight extent underneath the peduncles.

The Anterior or Superior Medullary Velum (Valve of Vieussens) (velum medullare anterius) (Figs. 584, 596, 605, and 606).—In the angular interval left between the two superior peduncles is a thin lamina of white matter, continuous with the white centre of the cerebellum, which bridges across from one peduncle to the other, and so completes the roof of the superior part of the ventricle. This is the superior medullary velum or valve of Vieussens. Its dorsal surface is covered by the folia of the lingula, already described (p. 928).

The Posterior or Inferior Medullary Velum (velum medullare posterius).—The posterior or inferior medullary velum is a thin layer of white substance, prolonged from the white centre of the medulla on either side of the nodule, which assists in forming a part of the roof of the fourth ventricle, stretching over it toward its lateral angles. It is continuous with the white substance of the cerebellum by its convex edge, while its thin concave margin is apparently free. In reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downward from the velum to the edge of the lingula.

The Tela Chorioides Inferior (tela chorioides ventriculi quarti).—The tela chorioides inferior is a layer of pia mater which covers in the lower part of the fourth ventricle below the inferior medullary velum. Superiorly it is reflected on to the under surface of the cerebellum, while inferiorly it is continued on to the restiform bodies and lower part of the medulla. This part of the roof of the ventricle contains no nervous matter, but consists merely of the ventricular epithelium covered by pia mater. The tela chorioides inferior, like the velum interpositum or tela chorioides superior (p. 855), really consists of two layers, which become more or less adherent, viz., that covering the under surface of the cerebellum and that covering the epithelium. It also possesses on each side a choroid plexus (plexus chorioides ventriculi quarti), which projects into the ventricular cavity invaginating before it the epithelial lining. Each plexus consists of a vertical portion which extends forward, near the
middle line, from the foramen of Majendie, and of a *transverse part*, which passes outward into the lateral recess of the ventricle as far as the foramina of Key and Retzius. The two plexuses present the form of a T, the vertical limb of which is, however, double, \[||\]. The tela does not form a complete membrane, for in it there are three openings: one in the middle line at the inferior angle of the ventricle, just above the position of the opening of the central canal of the cord; this is the *foramen of Majendie* (*apertura medialis ventriculi quarti*); the other two are at the right and left extremities of the lateral recesses of the ventricle, and each is named the *foramen of Key and Retzius* (*apertura lateralis ventriculi quarti*) (see pp. 852 and 853). Through these foramina the ventricles of the brain communicate with the subarachnoid space.

**The Obex.**—The obex is a thin, triangular lamina of gray matter, continuous below with the anterior gray commissure of the cord, which fills in the angle between the two diverging fasciculi graciles for a short distance.

**The Ligula.**—The ligula (*taenia ventriculi quarti*) are narrow bands of white matter, which project from the internal border of the funiculi graciles. They at first run upward and forward, and then turn outward over the restiform bodies, as far as the lateral recesses of the ventricle. Their inner borders are continuous with the epithelial roof of the ventricle.

**The Floor or Anterior Wall of the Fourth Ventricle (fossa rhomboidea)** (Figs. 599, 604, and 606).—The floor of the fourth ventricle is rhomboidal in shape,

and is traversed by a *vertical median fissure* (*sulcus longitudinalis fossae rhomboideae*), which below is continuous with the central canal of the spinal cord. At the junction of the fourth ventricle with the central canal of the cord is a dilatation or ampulla called the *ventricle of Arantius*. At the widest part of the fourth ventricle, opposite the level of the lateral recesses, it is marked by some transverse white lines, the *striae medullares* or *striae acusticae*. These consist of white fibres, which emerge from the longitudinal sulcus, and pass outward across the floor of the ventricle. Most of the striae acusticae take origin from cochlear nucleus, but some arise from the cochlear root. Most of them pass to the trape-
zium and lateral fillet of the opposite side, but some become external arciform fibres (Koelliker). These striae divide the floor of the ventricle into two triangles, inferior and superior.

The Inferior Triangle (Fig. 606).—The inferior triangle, or lower or posterior half of the floor, presents above an angular groove, the fovea inferior, the apex of which is at the striae, while the two limbs diverge below, and form the sides of a triangular dark area, termed the ala cinerea, which becomes elevated into a prominence below (eminencia cinerea). This area corresponds with the nuclei of the vagus and glossopharyngeal nerves, and is therefore termed the trigonum vagni. A second triangular area lies between the inner limb of the fovea and the median sulcus; its base is directed upward, and limited by the stria medullaris. It is termed the trigonum n. hypoglossi, because it corresponds in position to the tract of nerve-cells from which the hypoglossal nerve takes origin. A third triangular area to the outer side of the fovea inferior is named the trigonum acustici (area acustica). It lies between the groove forming the outer boundary of the fovea inferior and the lateral wall of the ventricle, and, like the trigonum hypoglossi, has its base directed upward. Here it is continuous with a prominence, the tuberculum acusticum, which extends into the anterior part of the floor of the ventricle.

The Superior Triangle (Fig. 606).—The superior triangle or upper or anterior half of the floor of the fourth ventricle, i.e., the part above the striae medullaris, presents in the middle line the continuation of the median longitudinal sulcus. On either side of this is a spindle-shaped longitudinal eminence, prominent in its centre, but less so above and below. This is the eminentia teres or fasciculus teres (colliculus facialis), and is produced by an underlying bundle of white fibres, the fasciculus teres (eminencia medialis), formed, in part at all events, by the fibres of the facial nerve. Immediately above and to the outer side of the eminentia teres is an angular depression, the fovea superior; this is sometimes crossed by a whitish band of fibres, the conductor sonorus, which is connected below with the striae medullares of the same side. Above the fovea is a bluish depressed area, the locus caeruleus. Its color is due to some pigmented nerve-cells, showing through the white covering of the floor. These pigmented cells are named the substantia ferruginea, and in them one of the roots of the fifth nerve terminates.

The Lining Membrane.—The lining membrane of the fourth ventricle is continuous above with that of the third ventricle, through the aqueduct of Sylvius (p. 912), and below with that of the central canal of the spinal cord. The cavity of the ventricle communicates below with the subarachnoid space by means of the foramen of Majendie and the foramina of Key and Retzius, already described.

The Internal Structure of the Medulla Oblongata (Figs. 607, 608, 609, 610, 611, 612).

If the cranial nerves emerging from the medulla are traced into its substance, it will be seen that they divide each half of the bulb into three wedge-shaped areas, which are named the anterior, lateral, and posterior areas of the medulla, and each of which corresponds to one of the subdivisions already described on the surface of this portion of the encephalon.

The Anterior Area.—The anterior area comprises that portion which is situated between the anterior median fissure and the fibres of superficial origin of the hypoglossal nerve. On the surface of the medulla this area corresponds to the pyramid (Fig. 607).

The Lateral Area.—The lateral area is situated between the fibres of superficial origin of the hypoglossal nerve on the one hand, and the fibres of superficial origin of the glossopharyngeal pneumogastric and spinal accessory nerves on the other. On the surface of the medulla, in its lower part, this area is single, and is
called the lateral tract; but in the upper part an oval-shaped body, the olivary body, comes forward between it and the pyramid, pushing aside the lateral tract (Fig. 607).

The Posterior Area.—The posterior area comprises that portion which is situated between the fibres of superficial origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves, and the posterior median fissure. On the surface of the medulla this area is marked by slight furrows, splitting it up into smaller columns; those in the lower part of the medulla are named, from without inward, the fasciculus of Rolando, the fasciculus cuneatus, and the fasciculus gracilis; in the upper part of the medulla they are replaced by the restiform body. Finally, the halves of the medulla are separated from each other by a median septum or raphé (Fig. 607).

Each of these three areas is made up of gray and white matter. The gray matter is derived for the most part from that of the cord. In like manner the white matter is partly made up of longitudinal fibres continuous with those of the cord, and partly of transverse fibres which intersect them.

In order to understand the internal structure of the medulla, it is necessary to describe the appearances as they are seen in the upper and lower portions of the medulla, since they differ considerably in these two parts.

The Lower Part of the Medulla (Figs. 608 and 609).—The first change in the internal structure is caused by the passage of the fibres of the crossed pyramidal tract obliquely through the gray matter of the anterior horn. As stated above, the pyramid is composed of fibres derived from the direct pyramidal tract of the anterior column of the cord of the same side, and from the crossed pyramidal tract of the lateral column of the opposite half of the cord. Those fibres which are derived from the direct pyramidal tract and which in the cord lie close to the median fissure are in the medulla placed to the outer side of the pyramid, being pushed aside, as it were, by the interpolation of the fibres derived from the crossed pyramidal tract, which
are much more numerous. The crossed pyramidal fibres ascend from the lateral column of the spinal cord, and, passing through the anterior gray cornu and across the middle line, form the inner part of the pyramid. In consequence of this passage of white fibres through its substance the anterior gray cornu is broken up into a coarse network, while one portion of it, the caput cornu, is entirely separated from the rest; only the base of the cornu remains intact, close to the ventrolateral aspect of the central canal. The caput cornu, thus separated, is displaced laterally, and comes to lie close to the caput cornu posterioris, which has also shifted its position. In consequence of this breaking up of the greater part of the anterior gray cornu by white fibres a coarse network is formed in the anterior and lateral areas of the medulla, which is named the formatio reticularis (Fig. 607).

The posterior cornu also undergoes somewhat similar changes. It becomes subdivided by the passage through it of the sensory fibres of the columns of Goll and Burdach. These pass across to the opposite anterior area of the medulla, where they are seen to lie immediately on the dorsal aspect of the pyramids. In their passage through the posterior horns of gray matter the latter become subdivided, in a manner somewhat similar to what has been seen to occur in the anterior horns. This crossing of the sensory fibres is termed the superior pyramidal or sensory decussation (Fig. 605). The caput cornu is displaced outward, so as almost to reach the surface, where it forms a projection, the fasciculus of Rolando, which enlarges above into a distinct prominence, the tubercle of Rolando (Fig. 607). Above the level of the tubercle of Rolando the caput cornu is separated from
the surface by a band of fibres termed the *ascending root of the fifth nerve* (*tractus spinalis n. trigemini*) and by the external arcuate fibres (Fig. 607). The neck of the cornu becomes broken up into a reticular formation by the decussation of the columns of Goll and Burdach, and by this means the caput is separated from the rest of the gray matter. The base of the cornu increases in size, and, as the central canal expands into the fourth ventricle, becomes pushed outward, and portions of it extend into the fasciculus gracilis and cuneati, and produce externally the eminences of the clava and cuneate tubercle. A third portion of the base becomes separated from the rest, and is placed outside the nucleus of the fasciculus cuneatus. This is called the *accessory cuneate nucleus*, and is supposed to be a continuation upward of Clarke's vesicular column of the cord.

**The Upper Part of the Medulla** (Figs. 607, 611, and 612).—The upper part of the medulla comprises the portion which enters into the formation of the floor of the fourth ventricle, where, in fact, the upper end of the central canal has opened out into this cavity. In this region the formatio reticularis is confined chiefly to the anterior and lateral areas. In the ventral portion of the posterior area there is only a small amount of reticular formation, but in addition to this there are individual masses of cells scattered among the longitudinal fibres.

**The Formatio Reticularis** (Fig. 607).—The formatio reticularis is a network of white matter in the deep portion of the medulla, the network containing...
gray matter. It is situated behind the pyramid and olivary body, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the floor of the fourth ventricle. It presents a peculiar reticulated appearance, from which it derives its name, and which is due to the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others transverse. The formatio reticularis presents a different appearance in the anterior area from what it does in the lateral area. In the former there is almost an entire absence of nerve-cells in the reticulated network, and hence it is known as the **formatio reticularis alba**; whereas, in the lateral area, the nerve-cells are numerous, and, as a consequence, this part is known as the **formatio reticularis grisea**. In the substance of the formatio reticularis is a small nucleus of gray matter. It is situated near the dorsal aspect of the hilum of the olivary nucleus, and has been named the **inferior central nucleus**. The formatio reticularis contains both longitudinal and transverse fibres. In the anterior area the longitudinal fibres may be arranged in two well-defined sets: (1) One set lies immediately behind the pyramid, and is named the **interolivary fillet** or **lemniscus (lemniscus interolivaris)** (Fig. 610). The fibres of the fillet are chiefly derived from the cells of the gracile and cuneate nuclei (Fig. 607), and may therefore be regarded as relay fibres of the columns of Goll and Burdach of the spinal cord, which terminate in synapses around the cells of the gracile and cuneate nuclei. They are prolonged inward and forward across the middle line forming the **superior pyramidal** or **sensory decussation** or the **decussation of the fillet** (Fig. 605). (2) The other set is continuous from the antero-lateral ground bundle of the cord, and a portion of these fibres forms the **posterior longitudinal bundle (fasciculus longitudinalis medialis)**, already referred to (p. 908). Both these sets of fibres are continued upward into the pons and mid-brain. The longitudinal fibres of the reticular formation in the lateral area are not arranged in distinct bundles. They are derived from the lateral column of the cord, after the crossed pyramidal tract has passed over to the opposite side. The longitudinal fibres of the posterior area are merely indeterminate fibres of the formatio reticularis, with the exception of two distinct bundles, which may be regarded as ascending roots of the fifth nerve (Fig. 607) and vago-glossopharyngeal nerves; the latter is termed the **fasciculus solitarius** (Fig. 607).

The **Transverse Fibres** of the reticular formation are the arched or arcuate fibres. The **external arciform or arcuate fibres** have already been described. The **internal arciform or arcuate fibres (fibræ arcuatae internæ)** are more numerous than the superficial set; they traverse nearly the whole area of the upper half of the medulla, except the pyramid. They pass from the raphe; some become superficial and join the external arciform fibres, while others remain deep and pass to the olivary body, the restiform body, and to the nuclei of the fasciculus cuneatus and fasciculus gracilis.

**Independent Nuclei** (Fig. 613).—In the upper part of the medulla are several independent nuclei of gray matter, which may be divided into two sets: (1) those which are traceable from the gray matter of the spinal cord, and (2) those which are not represented in the cord. The former are the hypoglossal nucleus, the nucleus of the fasciculus teres, and those of the auditory, glossopharyngeal, vagus, and spinal accessory nerves. The latter are the nucleus of the olivary body and the accessory olivary nuclei. In addition to these, small collections of gray matter are to be found in the median septum or raphe.

The **Hypoglossal Nucleus** (Figs. 607, 612, and 613).—The base of the anterior horn, which in the lower part of the medulla was situated on the ventro-lateral aspect of the central canal, now approaches the floor of the ventricle, where it lies close to the median sulcus under the fasciculus teres. In it is a column of large nerve-cells, from which the roots of the hypoglossal nerve are derived. It is accordingly designated the **hypoglossal nucleus**.
The Auditory Nuclei (Fig. 613).—Toward the upper part of the medulla, a considerable tract of gray matter may be found lying immediately beneath that portion of the floor of the fourth ventricle which is known as the trigonom acustici. This is the dorsal or inner auditory nucleus, and it lies just external to the vagoglosso-pharyngeal nucleus. In addition to this there is a small collection of nerve-cells on the ventral surface of the restiform body, between the two roots of the auditory nerve, which is known as the accessory or ventral auditory nucleus. On the outer side of the restiform body is a mass of cells associated with the cochlear root of the auditory nerve. This mass is termed the lateral acoustic tubercle or ganglion radicis cochlearis.

Nuclei of the Glosso-pharyngeal and Vagus Nerves (Fig. 613).—These are two in number, principal and accessory. The principal nucleus of the two nerves lies beneath that portion of the floor of the fourth ventricle which is known as the ala cinerea and fovea inferior. They form an oblong mass of gray matter, above the nucleus of the spinal accessory and lateral to the hypoglossal nucleus. The accessory nuclei are situated in the reticular formation of the posterior area, some distance from the floor of the fourth ventricle. They consist of a pear-shaped mass of cells, which is connected with the rest of the gray matter by a sort of stalk or peduncle, and was formerly known as the nucleus ambiguus (Fig. 607).

Nucleus of the Spinal Accessory Nerve (Fig. 613).—This nucleus consists of a group of cells, which is situated partly in the lower part of the medulla at the base of the posterior horn and close to the central canal. It extends upward,
lying beneath the lower part of the floor of the fourth ventricle and on the outer side of the hypoglossal nucleus.

The Nucleus of the Olivary Body (nucleus olivaris inferior) (Fig. 607).—When the olivary body is cut across, it is seen to be covered externally by white fibres, and internally to consist of a gray layer. The fibres which invest the nucleus are derived from the antero-lateral ground bundle. The gray layer is the nucleus of the olivary body, or, as it is sometimes called, the corpus dentatum of the olive. It is composed of a thin, wavy lamina, which is arranged in the form of a hollow capsule, open at its upper and inner part, and presenting a zigzag or dentated outline. Microscopically examined, the olivary nucleus is seen to consist of small, rounded, yellowish nerve-cells embedded in a matrix of neuroglia and fine nerve-fibres. White fibres, which can be traced from the raphé, and are probably derived from the opposite olive, enter the interior of the capsule by the aperture at its upper or inner part, these fibres constituting the olivary peduncle. The olivary peduncle is the lower portion of the cerebello-olivary tract (fibrae cerebelloolivares). This tract connects the cerebellar hemisphere with the opposite olivary nucleus.

The fibres of the olivary peduncle as they enter the olivary body diverge and some are lost in the gray matter of the olivary nucleus; others pass through it, and of these some turn backward to join the restiform body, and pass to the cerebellum as internal arcuate fibres; while others pierce the white matter of the olivary body and, reaching the surface, are continued to the restiform body as external arcuate fibres. The nucleus receives the olivary bundle of the spinal cord, the group of fibres called the triangular tract of Helwig. The central tegmental tract arises in the olivary nucleus and passes to the lenticular nucleus. The olivary nucleus receives another descending tract besides the cerebello-olivary, namely, the vestibulo-olivary (Santee). From the nucleus fibres pass by way of the lateral column to the anterior cornu of the same side of the spinal cord. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

Accessory Olivary Nuclei (Fig. 607).—Two small isolated masses of gray matter are to be found, one on the mesial and the other on the dorsal aspect of the corpus dentatum. These are the medial or internal accessory olivary nucleus (nucleus olivaris accessorius medialis) and the external or lateral accessory olivary nucleus (nucleus olivaris accessorius dorsalis). They are connected with the restiform body by some of the internal arcuate fibres. The fibres of the hypoglossal nerve, as they traverse the bulb, pass between the medial accessory nucleus and the chief olivary nucleus.

The Raphé (Fig. 607).—The raphé is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions, which can only be seen in suitable microscopic sections, thus: 1. Some are antero-posterior; these in front are continuous with the superficial arciform fibres. 2. Some are longitudinal; these are derived from the arciform fibres, which on entering the raphé change their direction and become longitudinal. 3. Some are oblique; these are continuous with the deep arciform fibres which pass from the raphé.

The nerve-cells of the raphé are multipolar; some are connected with the antero-posterior fibres, others with the superficial arcuate fibres.

Weight of the Encephalon.—The average weight of the brain in the adult male is 49½ oz., or a little more than 3 lbs. avoirdupois; that of the female 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain in the male ranges between 46 oz. and 53 oz., and in the female between 41 oz. and 47 oz. In the male the maximum weight out of 278 cases was 65 oz., and the minimum weight 34 oz. The maximum weight of the adult female brain out of 191 cases was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1424 grammes (about.45 oz.),
of a woman's 1272 grammes (about 41 oz.), and, according to Krause, 1570 grammes (about 48½ oz.) for the male and 1350 (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes. Marshall concluded that if woman is judged by her height only, she has a smaller amount of cerebral matter than has man; if she is judged by her weight alone, she has more; but if both sexes are gauged by both standards, their "cerebral endowment is seen to be practically equal."

The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of Daniel Webster 63⅔ oz., that of Dr. Abercrombie 63 oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldeman, of Cincinnati, has recorded the case of a mulatto, aged forty-five, whose brain weighed 68⅓ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. James Morris recorded the case of a bricklayer, who could not read or write, whose brain weighed 67 oz. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. In not a few instances the brains of very able men have been of average weight or of less than average weight. The brain of Samuel D. Gross, the surgeon, weighed 48 oz., the brain of Gambetta, the statesman, 40½ oz., the brain of Walt Whitman, the poet, 43.3 oz., the brain of Hughes Bennett, the physician, 47 oz., the brain of Joseph Leidy, the naturalist and anatomist, 49.9 oz., and the brain of Döllinger, the physiologist, 42.6 oz. M. Nikiforoff has published an article in the Novosti on the subject of the weight of brains. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. There seems to be a relation between the weight of the brain and the body weight and stature. Quain gives the ratio between the brain weight and body weight as 1 to 41 in healthy individuals, but this proportion is by no means fixed and seems to vary widely in either direction. As the stature increases the brain weight increases, but, as Mills says, "taller persons have relatively less brain matter than shorter ones, although absolutely they have more." The significance of the weight of the brain also depends upon the cause of death, for long illness or old age wastes the brain. To define the real degree of development of the brain, it is therefore necessary to have a knowledge of the condition of the whole body, and, as this is usually lacking, the mere record of weight possesses little significance. As Mills says: "Apparently there is no invariable nor necessary relation between mere brain weight and the degree of individual intelligence; but high brain weights occur in larger proportions among civilized than among uncivilized races." Furthermore, it is to be remembered that a heavy brain may be a diseased brain. For instance, Byron's brain weighed nearly 64 oz. and showed evidences of disease.

The human brain is heavier than the brain of any of the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

CEREBRAL LOCALIZATION AND TOPOGRAPHY.

The cortex of the brain is highly specialized, and different regions represent special functions. In it are represented "the numerous manifestations associated with consciousness;" in it memories are stored up; and "in it occur the last and highest bodily processes concerned with sensations received from without, and with the setting free of impulses which are projected to lower centres and to the outside world." A centre is an aggregation of nerve-cells and fibres, which "aggregation represents physiologically some action" (Mills). Physiological and pathological researches and surgical operations have proved that the surface of the brain may be mapped out into series of definite centres, each one of which is intimately connected with some well-defined function. A group of centres is known as a zone, an area, or a region. As Hughlings Jackson says, the study of centres is an investigation into the anatomical "substrata" of visual, motor, tactile, and other ideas; of "the parts which represent impressions of sight, of touch, of movement, and other functions" (Mills). Certain cortical centres are known as motor centres. Stimulation of these centres causes movement. Destruction of these centres renders movement impos-

Fig. 614.—Drawing to illustrate cranio-cerebral topography. (Taken from a cast in the Museum of the Royal College of Surgeons of England, prepared by Professor Cunningham.)

sible. The centres are associated with contraction of muscular groups producing special movements not with the contraction of individual muscles. They represent movements rather than muscles. These centres are found particularly around the fissure of Rolando and on the mesial surface of the hemisphere, and they are associated with movements of the extremities of the opposite side of the body, and movements of the face, mouth, and tongue. Mills, von Monakow, and Sherrington are of the opinion that the motor areas are entirely in front of the fissure of Rolando (Figs. 615 and 616). This view is highly probable, but is not absolutely proved. Other observers hold that the motor areas occupy the entire ascending frontal and ascending parietal convolutions, extend a little way forward into the third frontal convolution and backward into the superior parietal convolution. The motor areas certainly extend on to the mesial surface in the paracentral lobule and pass perhaps into the marginal convolution. On the convexity of the hemi-

sphere the highest centre is the leg area. Below this, in the order named, are the centres for the arm, face, lips, tongue, larynx, and pharynx. On the mesial surface from before backward are areas for the head, shoulder, trunk, hip, knee, leg, and foot. The centres for head and eye movements are in front of the arm centre. In a large motor area there are certain smaller areas. For instance, the area for the lower extremity contains separate centres, representing movements of the hip, knee, leg, foot, and toes.

The arm centre contains centres for movements of the shoulder, arm, wrist, thumb, and fingers. The face centre contains centres for movements of the upper face, the lower face, the lips, and tongue. The somesthetic area or the area of general sensation is not certainly marked out. Those who believe that the motor area is both front and back of the Rolandic fissure maintain that the area of general sensation largely corresponds to the motor area, but is of greater extent as it enters into the limbic lobe. Mills places it back of the fissure of Rolando in the convexity and also on the mesial surface of the hemisphere.

The cortical centres are shown in Figs. 617 and 618. This is not the place, nor can space be given, to describe these localities.

Cranio-cerebral Topography.—The position of the principal fissures and convolutions of the cerebrum and their relation to the outer surface of the scalp (Fig. 614) have been the subject of
much investigation, and many systems have been devised by which one may localize these parts from an explanation of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons; in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull’s area.

![Diagram](image)

*Fig. 617.—The localization of various centres on the outer surface of the left side of the human brain. (American Text-book of Surgery.)*

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 149), and the relation of the fissures and convolutions to these landmarks is as follows:

**Longitudinal Fissure** (Fig. 619).—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

**The Fissure of Sylvius** (Fig. 619).—The position of the fissure of Sylvius and its posterior horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is therefore two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

**The Transverse Fissure or Fissure of Bichat.**—This is between the cerebrum and cerebellum and corresponds to a line drawn from the inion to the external auditory meatus (the line $BC$ in Fig. 619).
**Fissure of Rolando.**—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the sulcus will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method, but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for $\frac{3}{4}$ inches, its axis making an angle of 67° with the middle line. Cunningham states that this angle more nearly averages 71.5°. In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction and $\frac{3}{4}$ inches will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrtometer, which combines the scale of measurements for localizing the fissure with data for representing its length and direction.\(^1\) Professor Thane gives the lower end of the furrow as

\[\text{Fig. 619.—Relations of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp.} \quad (\text{Reid.})\]

"close to the posterior limb, and about half an inch behind the bifurcation of the fissure of Sylvius." So that, according to this anatomist, a line drawn from a point half an inch behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the fissure of Rolando. Dr. Reid adopts a different method (Fig. 619). He first indicates on the surface the longitudinal fissure and the horizontal limb of the fissure of Sylvius (as above). He then draws two perpendicular lines from his "base-line" (that is, a line from the lowest part of the infraorbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (DE, Fig. 619) from the depression in front of the external auditory meatus, and the other (FG, Fig. 619) from the posterior border of the mastoid process at its root. He has thus described on the surface of the head a four-sided figure (F D G E, Fig. 619), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the fissure of Sylvius will represent the furrow.

The **Parieto-occipital Fissure** on the upper surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about an inch, from a point one-fifth of an inch in front of the lambda (posterior fontanelle). Reid states that if the horizontal limb of the fissure of Sylvius be continued onward to the sagittal suture, the last inch of this line will indicate the position of the sulcus (Fig. 619).

\(^1\) Lanceet, 1888, vol. i. p. 408.
The Pre-central Sulcus begins four-fifths of an inch in front of the middle of the fissure of Rolando, and extends nearly, but not quite, to the horizontal limb of the fissure of Sylvius.

The Superior Frontal Fissure runs backward from the supraorbital notch, parallel with the line of the longitudinal fissure to two-fifths of an inch in front of the line indicating the position of the fissure of Rolando.

The Inferior Frontal Fissure follows the course of the superior temporal ridge on the frontal bone.

The Intraparietal Fissure begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the posterior fontanelle and the parietal eminence.

Fig. 620.—Kronlein’s method for determining the situations of certain fissures of the brain.

Kronlein’s method for determining the situations of certain fissures of the brain is very useful and easy of application (Fig. 620). It is as follows: (1) The base line, $ZM$, is a horizontal line running at the level of the lower border of the orbit and the upper border of the external auditory meatus. (2) Another horizontal line, $KK'$, is drawn parallel to $ZM$. The second horizontal line is on a level with the supraorbital ridge. (3) A vertical line, $ZK$, is erected from $ZM$ at the middle of the zygoma and is carried to the line, $KK'$. (4) Another vertical line, $AR$, is erected from the base-line at the level of the articulation of the mandible and is carried to $R$. (5) A third vertical line, $MP$, is erected from the base-line at the posterior border of the mastoid process and is carried to the middle line of the skull, which is marked $P$. (6) A line is drawn from
THE NERVOUS SYSTEM

$K$ to $P$. The portion of this line between $R$ and $P'$ corresponds to the fissure of Rolando. (7) The angle $P \ K \ K'$ is bisected by the line $K \ S$. $K \ S$ corresponds to the fissure of Sylvius from its bifurcation to its termination posteriorly, and $K$ is directly over the bifurcation. To reach the anterior branch of the middle meningeal, apply the trephine at $K'$ to reach the posterior branch, apply it at $K'$. In abscess of the temporo-sphenoidal lobe the trephine should be applied, according to von Bergmann, in the region $Aa \ K'$ $M$.

THE NERVE-PATHS.

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the course taken by its more important nerve-paths, and of the direction in which impulses pass along them. Before doing so, however, it is necessary to refer to the methods employed in elucidating this complex subject. All nerve-fibres may be regarded as outgrowths from nerve-cells, and it is found that if a nerve-fibre be cut, the portion of it which is severed from the cell undergoes degeneration and becomes atrophied. Until recent years it was believed that the cell itself showed no change under such circumstances. This, however, is not the case, for if a nerve, the sciatic, for instance, be divided in an animal, and after an interval of some weeks the animal be injected with methylene blue and killed, it will be seen, on examining sections of the lumbar region of the spinal cord, that the cells are stained imperfectly or not at all, owing to a diminution, or, it may be, an entire disappearance of the chromatin, a substance which, in a normal cell, shows marked affinity for staining reagents. Further, the body of the cell is swollen, the nucleus displayed toward the periphery, and the part of the axone still attached to the altered cell is diminished in size and somewhat atrophied. Under favorable conditions the cell is capable of reassuming its normal appearance and the axone may commence to grow. This method of study by injection of methylene blue is of great value in determining the origin of nerve-fibres from their cells. Again, electrical stimulation of certain localized areas of the brain or of the tracts arising from them is followed by the contraction of the muscles of the body. The cortical centres of the motor tracts are situated in the convolutions adjacent to the fissure of Rolando (page 953). When the stimulus is applied to one part of the motor area the muscles of one limb of the opposite contract, while other portions control the movements of the other limb of the opposite side, etc. Destruction of these parts entails loss of function, paralysis of muscles, and degeneration of the tracts below the seat of injury. During life injury and disease may give rise to symptoms resembling either the effects of stimulation or those of destruction; and after death the tracts, or the centres of the tracts, are seen to be degenerated or otherwise altered. It was long believed by all and is still maintained by many that the motor area includes the ascending parietal, ascending frontal, and superior parietal convolutions. Mills, von Monakow, Sherrington and other high authorities now teach that the motor region is entirely in front of the central fissure, with the possible exception that the gyrual mass between the foot of the fissure of Rolando and the Sylvian fissure, and extending a little back of the line of the central fissure, which may be included in the area for the face (Charles K. Mills) (Figs. 615 and 616). The motor areas are separated from each other and do not overlap, but probably interdigitate (Mills). The same is true of the areas for cutaneous sensibility. By observing the development of the nervous system during the growth of the embryo, the fact is disclosed that all axis-cylinders do not acquire a medullary sheath at one and the same time. Speaking generally, it may be said that afferent fibres become medullated before efferent, and that in the case of the latter myelination occurs earlier in the brain than in the cord. By watching the effects of these different processes the functions of a considerable part of the brain and of the nerves leading from or to it have been determined.
The Motor, Efferent, or Descending Tract (Figs. 621, 622, and 623).—The constituent fibres of this tract are the axis-cylinder processes of cells situated in the cortex of the convolutions about and probably solely in front of the fissure of Rolando. At first they are somewhat widely diffused, but as they descend through the corona radiata they gradually approach each other and pass between the lenticular nucleus and optic thalamus in the genu and anterior two-thirds of the posterior limb of the internal capsule. Proceeding downward they next occupy the middle three-fifths of the pes or crus of the crus cerebri, and enter the pons Varolii, where the transverse fibres of this body not only conceal them, but divide them up into irregular bundles. Eventually they reach the medulla, and here the motor tracts form the anterior pyramids which lie one on each side of the median fissure. The transit of the fibres from the medulla is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the decussation of the pyramids (Figs. 594, 605, 609, 621, 622, and 623), and descend in the opposite side of the cord as the indirect or crossed pyramidal tract (Figs. 605 and 623). Throughout the length of the spinal cord fibres from this column pass into the gray matter, to terminate by ramifying around the cells of the anterior horn. The more laterally placed portion of the motor tract does not decussate in the medulla, but descends as the direct or uncrossed pyramidal tract (Fig. 605); these fibres, however, end in the anterior gray horn of the opposite side of the spinal cord by passing across in the anterior white commissure. 1. Motor and inhibiting influences which reach the spinal nerves arise in the upper three-fourths of the motor area in front of the Rolandic fissure, pass along the fibres of the corona radiata.
and of the anterior two-thirds of the posterior limb of the internal capsule, the middle three-fifths of the crista, the anterior or ventral pontine fibres, and the medullary pyramids. From this point they may pass along either the crossed or the uncrossed pyramidal tract to reach the gray horn of the opposite side of the spinal cord. "By the former route the impulses cross over in the medulla, through the decussation of the pyramids, and descend in the lateral column of the spinal cord; but by the uncrossed route they descend in the anterior column of the cord and decussate in succession through the white commissure. Impulses by either route finally reach the anterior gray cornu of the spinal cord, and, with the exception of a small percentage of them, they reach the cornu opposite to their Rolandic origin. The few uncrossed fibres in the crossed pyramidal tract conduct uncrossed impulses to the anterior cornu of the same side." 2. Motor and inhibiting influences which reach the cranial nerves arise in the lower portion of the motor area, pass through the corona radiata and posterior two-thirds of the internal capsule, but deviate from the pyramidal tract before reaching the medulla, and pass to the nuclei of cranial nerves (Fig. 623). On the same side fibres pass to the nuclei of the fourth nerve, but the balance of the fibres cross and pass to nuclei on the opposite side—viz., the nuclei of the third, fifth, sixth, seventh, ninth, tenth, eleventh, and twelfth cranial nerves.

The Cerebro-cortico-pontal Paths.—These paths pass through the cerebellum. Impulses from the prefrontal region pass along the corona radiata, through the anterior limb of the internal capsule and the inner portion of the crista. Impulses from the temporal region pass along the corona radiata, through the posterior limb of the internal capsule and the outer portion of the crista. The nucleus pontis and cranial nerve nuclei of the same side receive the impulses from both the frontal and the temporal paths, and from these depots the impulses are sent to cranial nerves or to spinal nerves. To cranial nerves they are sent direct from the synapses about the nuclei. In order to reach spinal nerves they pass to the cerebellar cortex by means of the middle peduncle of the cerebellum. From the cerebellar cortex the impulses pass through the inferior peduncles of the cerebellum and the lateral region of the medulla to reach the anterior gray horn (by way of the antero-lateral descending cerebellar tract).

The Intermediate Crusta Path (by Way of the Intermediate Bundle).—Some impulses which arise in the cerebral cortex pass to the corpus striatum, then to the nucleus pontis of the same side (chiefly), then by way of the middle peduncle of the cerebellum to the cerebellar cortex, and then along the antero-lateral descending cerebellar tract.

The Red Nucleus Path.—Impulses from the cerebral cortex may reach the red nucleus by way of the optic thalamus (direct route) and by way of the corpus striatum (indirect route). Impulses which reach the red nucleus by the direct route travel along the crossed descending tract of the red nucleus to the centre of the gray matter in the crescent of the opposite side of the cord. Impulses which reach the red nucleus by the indirect route pass to the cerebellar cortex of the opposite side and from the cortex along the descending cerebellar tract.

Short Fibre Paths (chiefly in the formatio reticularis).—Santee presents a concise explanation of the course of impulses along these paths. 2 He describes five paths: 1. Impulses having reached the ganglia of the cerebrum and mesencephalon, pass along the formatio reticularis and reach the antero-lateral ground bundle of the spinal cord to ultimately reach the spinal nerves. Impulses leaving the formatio reticularis may reach motor cranial nerve nuclei. 2. Impulses may pass from the formatio in the pons and by way of the middle cerebellar peduncle

---

1 Anatomy of the Brain and Spinal Cord. By Harris E. Santee.
2 Ibid.
reach the cerebellar cortex. 3. Impulses which reach the cerebellar cortex may reach the antero-lateral ground bundle of the opposite side of the cord. 4. From the third cranial nerve nucleus fibres pass to the seventh nerve, and impulses come from the third nerve and are sent to the Occipito-fontalis, Corrugator supercilii, and Orbicularis palpebrarum muscles. 5. Fibres pass from the nucleus of the sixth cranial nerve to the nucleus of the opposite third nerve, and impulses pass from the nucleus of the sixth nerve of one side to the Internal rectus muscle of the opposite side.

**The Sensory, Afferent, or Ascending Tract (Figs. 624, 625, and 626). Path by the Columns of Goll and Burdach.**—The course taken by those fibres of the posterior nerve-roots which ascend has been arrived at by dividing the nerve-roots between their ganglia and their entrance into the spinal cord and subsequently examining the degenerated areas. It has been found that the fibres pursue an oblique course, being situated at first in the outer part of Burdach's column; higher up they occupy the middle of this column, being displaced inward by the accession of other entering fibres, while still higher they enter and are continued upward in the column of Goll. The upper cervical fibres do not reach the column of Goll, but are entirely confined to that of Burdach. The degeneration method proves that the localization of these fibres is very precise: the sacral nerves lying to the inner side of Goll's column and near its periphery; the lumbar nerves to their outer side; the dorsal nerves still more laterally; while the cervical nerves are confined to the outer part of Burdach's column.
On reaching the medulla these ascending fibres end by arborizing around the
cells in the gracile and cuneate nuclei, and the further upward course of the tract
is effected by the axis-cylinder processes of these cells. There are two paths from
this region, the direct and the indirect. The fibres of the direct path decussate in
the medulla, dorsal to the crossing of the motor tract, in what is termed the superior
pyramidal decussation, the sensory decussation, or the decussation of the fillet (Figs. 605,
610, 624, and 626), terms which are synonymous. Having crossed the middle line
they ascend through the pons and tegmentum of the crus cerebri, and, reaching the
ventral surface of the optic thalamus, from which they pass by the three systems of
Flechsig to the cortex. The impulses ascending from the optic thalamus pass to the
cortex through the internal capsule and corona radiata. Impulses which take the indirect path leave the medulla, pass to the cortex of the superior worm of the cerebellum,

and then through the superior peduncle to the optic thalamus and the red nucleus
of the opposite side. These fibres also reach the cortex by means of the systems
of Flechsig. The fibres of the sensory path are arranged as follows in the internal
capsule: those which go to the fronto-parietal cortex being situated in the extreme
front part of the anterior limb of the internal capsule, while in the hinder extremity
of the posterior limb other fibres pass to their distribution in the temporal and
occipital cortex.

Path of Cranial Nerves and Medial Fillet.—Common sensory impulses passing
along the fifth, the vestibular portion of the eighth, the ninth, and the tenth
nerves are conveyed by the medial fillet to the ventral portion of the opposite
optic thalamus, and from this region they are taken to the cortex by the systems of
Flechsig.
Paths by the Direct Cerebellar Tract.—The direct cerebellar tract begins about the level of the second lumbar vertebra, and is the continuation upward of the axis-cylinders of Clarke's column. At the upper end of the cord it passes into the restiform body and through this reaches the cortex of the superior vermis of the cerebellum. This tract seems to lose some of its fibres in the cord, since the area of degeneration resulting from a section of the lower part of the cord diminishes from below upward; only some of its fibres therefore pass directly to the cerebellum. On the other hand, the tract is reinforced by an accession of fibres from the cord itself, so that its transverse area is greater above than below. Impulses of equilibrium pass from the posterior roots of the spinal nerves and ascend along the direct cerebellar tract, chiefly to the cerebellar cortex of the same side, partly to the cerebellar cortex of the opposite side. From the cerebellar cortex they pass to the cerebral cortex by the route previously referred to.

The Path by the Antero-lateral Ascending Cerebellar Tract.—Ordinary sensory and thermic impulses ascend along this tract to the cerebellar cortex of the opposite side (the superior worm) and partly to the optic thalamus and parietal cortex.

Short Fibre Paths.—According to Santee there are three of these paths: 1. One path is in the antero-lateral ground bundle and formatio reticularis. It conveys sensory impressions from the gray matter of the cord or from pontine and medullary nuclei which receive fibres of common sensation from cranial nerves to the opposite optic thalamus. 2. Another path takes impulses from the formatio reticularis to the cerebellar cortex and then to the red nucleus and optic thalamus. 3. Impulses may leave the antero-lateral ascending cerebellar tract along fibres which diverge in the medulla. These impulses reach the lateral nucleus, pass to the cerebellar cortex, and finally attain the cerebral cortex.¹

Paths of Special Sensations.—(See the section on Cranial Nerves.)

Reflex Paths.—Reflex paths are almost infinite in number and only a few can be set forth. A spinal reflex action is produced as follows: A stimulus imparted to a sensory nerve ending is conveyed up the nerve to a centre or several centres in the spinal gray matter, from which it is transferred to a motor nerve, and by this to a muscle which responds to the stimulus by movement. Such a path is called a reflex arc.

Spinal Reflexes (Fig. 628) may be very simple or somewhat complicated. In the simple spinal reflex the cause of the stimulus is as indicated above. Among these simple spinal reflexes are the patellar reflex, the reflex withdrawal of a part when irritated, and the skin reflexes.

In a more complicated spinal reflex the "impulses traverse at least three neurones" (Santee). The more complicated reflexes are those of "defecation, mic-turition, parturition, vasomotor reflexes, cardio-accelerator reflexes, etc." (Santee).

A Cranial Reflex travels up a sensory cranial nerve and is transferred to a motor cranial nerve. Among these impulses are "watering" of the mouth on smelling a savory dish, the facial muscular contraction due to pain in the fifth nerve, coughing, sneezing, vomiting, and swallowing.

Spinal Cranial Reflexes are due to the ascent of impulses in the cord by way of the posterior longitudinal bundle or by Burdach's column, which impulses reach the nuclei of cranial motor nerves. "Thus is brought about the movement of the eyes toward the source of impulse, a change of facial expression to agree with the painful or pleasing character of the impulses, etc."² Cranial spinal reflexes are produced by impulses from cranial sensory nerves being transferred to spinal motor fibres. An example of one of these reflexes is the starting on hearing a sudden loud sound. Among these numerous reflexes are the respiratory, auditory, and pupillary.

Fig. 628.—Explanation of abbreviations: tr. ol., olfactory tract; c. g., lateral geniculate body; p. r. c., A. indicate approximately the location of the reflex centres for the pupillary (p), the respiratory (r), cremasteric (cr), patellar (pat), and tendon Achilles (A) reflexes. The vesical centre lies in the third and fourth sacral segments; the anal centre in the fourth and fifth (represented by circles); the centres for erection, ejaculation, labor pains (?) are probably also situated in this region. In reality, the divisions between the various segments are, of course, not so sharp as they are shown in the diagram, so that a given muscle or cutaneous region derives some of its controlling nerve-roots from the segments lying immediately above and below the principal segment. The sensory segment for any given region is regularly somewhat higher than the corresponding motor segment. (Jakob.)

**THE SPINAL NERVES (NERVI SPINALES).**

The spinal nerves are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged
into the following groups, corresponding to the region of the spine through which they pass:

- Cervical ........................................... 8 pairs.
- Thoracic or Dorsal .............................. 12 “
- Lumbar .............................................. 5 “
- Sacral .................................................. 5 “
- Coccygeal ........................................... 1 “

It will be observed that each group of nerves corresponds in number with the vertebrae in that region, except the cervical and coccygeal. Sometimes there is no thirty-first pair. Occasionally below the thirty-first pair there may be one or even two filamentous pairs which do not pass out of the spinal canal.

Each spinal nerve arises by two roots, an anterior or motor root and a posterior or sensory root, the latter being distinguished by a ganglion, termed the spinal ganglion.

The Roots of the Spinal Nerves (Figs. 538, 540, 541, 629, 630, 631).

The Anterior or Ventral Root (radix anterior).—The superficial origin is from the antero-lateral columns of the cord, corresponding to the situation of the anterior cornu of gray matter. Each root is composed of from four to eight filaments (filia radicularia).

The deep origin can be traced through the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the gray substance, where their fibrils diverge in several directions: some passing inward, are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornu of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass outward, to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column.

The Posterior or Dorsal Root (radix posterior).—The superficial origin is by filaments (filia radicularia), from the postero-lateral fissure of the cord. The real origin of these fibres is from the nerve-cells in the posterior root ganglion, from which they can be traced into the cord in two main bundles, the course of which has already been studied (p. 847).

The anterior roots are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles near the intervertebral foramina.

The posterior roots of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils
pass outward toward the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion (Figs. 629, 630, and 631) which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has occasionally no ganglion developed upon it, and when the ganglion exists, it is often situated within the dura mater. The first cervical may have a rudimentary posterior root or no posterior root.

Within the spinal canal the nerve-roots are separated from each other by the \textit{ligamentum denticulatum} (Fig. 629). In the cervical region the spinal portion of the spinal accessory nerve separates the roots. Each root obtains a covering of pia mater, which becomes continuous with the neurilemma; "the arachnoid invests each root as far as the point where it meets with the dura mater; the two roots, after piercing the dura separately, are enclosed by it in a single tubular sheath, in which is included the spinal ganglion of the dorsal root."\footnote{Cunningham's Text-book of Anatomy.}

The Ganglia of the Spinal Nerves (\textit{Ganglia Spinales}) (Figs. 629, 630, 631).

A ganglion is developed upon the posterior root of each of the spinal nerves. The ganglion upon the posterior root of the first cervical nerve may be rudimentary or absent. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate.
the dura mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglia upon the first and second cervical nerves form an exception to these characters, being placed on the arches of the vertebrae over which the nerves pass. The ganglia of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, is situated at some distance from the origin of the posterior root.

The ganglion in an embryo is composed of bipolar nerve-cells. In an adult the bipolar nerve-cells by fusion of their two poles form unipolar nerve-cells. The process of each unipolar cell divides into two a short distance from the cell. One of the processes from each cell passes to the spinal cord, and the other passes into the spinal nerve. On the dorsal roots of the lumbar and sacral nerves, between the spinal ganglia and the cord, small cellular masses occasionally exist. They are called accessory spinal ganglia (ganglia aberrantia).

Distribution of the Spinal Nerves.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed constitutes the spinal nerve; it passes out of the intervertebral foramen, and divides into a posterior primary division for the supply of the posterior part of the body, and an anterior primary division for the supply of the anterior part of the body (Fig. 630). Each division contains fibres from both roots.

Before dividing, each spinal nerve gives off a small recurrent or meningeal branch (ramus meningeus) (Fig. 630), which is joined by a filament from the communicating branch of the sympathetic (ramus communicans) (Fig. 630), which connects the ganglion with the anterior division. The meningeal branches unite and form one nerve, which passes inward through the intervertebral foramen and supplies the dura mater, sending branches to the vertebrae and vertebral ligaments.

The Posterior Primary Divisions (rami posteriores) (Fig. 630).—The posterior primary divisions of the spinal nerves are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots, in the intervertebral foramina; and, passing backward, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The posterior primary divisions of the spinal nerves form two small plexuses, the posterior cervical plexus and the posterior sacral plexus. The first cervical, the fourth and fifth sacral, and the coccygeal nerves do not divide into external and internal branches.

The Anterior Primary Divisions (rami anteriores) (Fig. 630).—The anterior primary divisions of the spinal nerves supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior primary divisions. Each division, soon after its origin, receives a slender filament from the sympathetic, which is called the gray ramus communicans. In the dorsal region the anterior primary divisions of the spinal nerves are quite separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution. The anterior primary divisions of certain dorsal, lumbar, and sacral nerves give off a delicate collection of nerve filaments to the sympathetic cord. These are called the white rami communicantes or the visceral branches of the spinal nerves.

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower
than the upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina.

The following table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebrae:

</table>

**THE CERVICAL NERVES (NN. CERVICALES).**

**The Roots of the Cervical Nerves.**

The roots of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule; it is smaller than the anterior root. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upward and outward; the second is horizontal; the others are directed obliquely downward and outward, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

**The First Cervical or Suboccipital Nerve** (n. suboccipitalis) (Fig. 632).—The posterior root may be rudimentary or absent. The trunk of the first cervical nerve leaves the spinal canal between the occipital bone and the posterior arch of the atlas (Figs. 16 and 202).

The **Trunk of the Second Cervical Nerve** leaves the spinal canal between the posterior arch of the atlas and the lamina of the axis; and the **Eighth** (the last), between the last cervical and first dorsal vertebrae.

Each nerve, at its exit from the intervertebral foramen, divides into a posterior and an anterior division. The anterior divisions of the four upper cervical nerves form the **cervical plexus.** The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the **brachial plexus.**

**The Posterior or Dorsal Divisions of the Cervical Nerves (Rami Posteriores)** (Fig. 633).

The **Posterior Division of the First Cervical Nerve** (Figs. 632 and 633) differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas,
lying beneath the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior and Obliquus inferior, and, by muscular branches, supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a communicating filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The Posterior Division of the Second Cervical Nerve is three or four times greater in diameter than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and an external branch.

The internal branch, called, from its size and distribution, the great occipital nerve (occipitalis major) (Figs. 632 and 633), ascends obliquely inward between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium. It is now joined by a filament from the posterior division of the third cervical nerve, the anastomotic, and ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an auricular branch to the back part of the ear and muscular branches to the Complexus.

The external branch is often joined by the external branch of the posterior division of the third cervical nerve, and supplies the Splenius, Trachelo-mastoid, and Complexus.

The Posterior Division of the Third Cervical Nerve (Figs. 632 and 633) is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve, to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an internal and external branch.

The internal or cutaneous branch passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle.
The **external branch** joins with that of the posterior division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The **third or least occipital nerve** (*n. occipitalis minimus* or *n. occipitalis tertius*) (Fig. 632) *arises* from the internal or cutaneous branch of the posterior division of the third cervical nerve, beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the **posterior cervical plexus**.

The **Posterior Divisions of the Fourth, Fifth, Sixth, Seventh, and Eighth Cervical Nerves** pass backward, and divide, behind the Intertransversales muscles, into **internal and external branches**.

The **internal branches**, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass
between the Complexus and Semispinalis muscles, and, having reached the spinal processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinalis, Multifidus spinææ, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld).

The external branches supply the muscles at the side of the neck—viz., the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

The Anterior Divisions of the Cervical Nerves (Rami Anteriores).

The Anterior Division of the First Cervical Nerve (Fig. 635) is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas it receives a filament from the sympathetic. It then descends in front of the transverse process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from the loop between this nerve and the second cervical nerve join the pneumogastric, the hypoglossal, and sympathetic, and some branches are distributed to the Rectus lateralis and the two Anteriors. The fibres which communicate with the hypoglossal simply pass through the latter nerve to become for the most part the descendens hypoglossi. According to Valentin, the anterior division of the suboccipital nerve distributes filaments to the occipito-atlantal articulation and to the mastoid process of the temporal bone.

The Anterior Division of the Second Cervical Nerve (Fig. 635) escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides in front of the Intertransverse muscle into an ascending branch, which joins the first cervical; and one or two descending branches, which join the third cervical. It gives off the small occipital; a branch to assist in forming the great auricular; another to assist in forming the superficial cervical; one of the communicantes hypoglossi, and a filament to the Sterno-mastoid, which communicates in the substance of the muscle with the spinal accessory.

The Anterior Division of the Third Cervical Nerve (Fig. 635) is double the size of the preceding. At its exit from the intervertebral foramen it passes downward and outward beneath the Sterno-mastoid muscle, and divides into two branches. The ascending branch joins the anterior division of the second cervical; the descending branch passes down in front of the Scaleni anticus muscle and communicates with the fourth cervical. It gives off the larger part of the great auricular and superficial cervical nerves; one of the communicantes hypoglossi; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the Levator anguli scapulae and Trapezius; this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the Scaleni medius is derived from this source.

The Anterior Division of the Fourth Cervical Nerve (Fig. 635) is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing downward and outward, divides into numerous filaments, which cross the posterior triangle of the neck, forming the supraclavicular nerves. It gives a branch to the phrenic nerve, while it is contained in the intertransverse space, and sometimes a branch to the Scaleni medius muscle. It also gives a branch to the Levator anguli scapulae and to the Trapezius, which unites
with the branch given off from the third nerve, and communicates beneath the muscle with the spinal accessory.

The Anterior Divisions of the Fifth, Sixth, Seventh, and Eighth Cervical Nerves are remarkable for their size. They are much larger than the preceding nerves, and are all of equal dimensions. They assist in the formation of the brachial plexus.

The Cervical Plexus (Plexus Cervicalis) (Figs. 634 and 635).

The cervical plexus is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebrae, resting upon the Levator anguli scapulae and Scalenus medius muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, superficial and deep, which may be thus arranged:

Superficial

- Ascending
  - Occipitalis minor.
  - Auricularis magnus.
  - Superficialis colli.
- Descending
  - Supracleavicular
  - Supracleavicular
  - Supra-acromial.
  - Communicating.
  - Muscular.
  - Communicantes hypoglossi.
  - Phrenic.

Deep

- Internal
  - Communicating.
- External
  - Communicating.
  - Muscular.

The Superficial Branches of the Cervical Plexus. The Small Occipital Nerve (n. occipitalis minor) (Fig. 634).—The small occipital nerve arises from the second cervical nerve, sometimes also from the third; it curves round the posterior border of the Sterno-mastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, the auricularis magnus, and with the posterior auricular branch of the facial.

This nerve gives off an auricular branch, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the auricularis magnus. The auricular branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The Great Auricular Nerve (n. auricularis magnus) (Fig. 634).—The great auricular nerve is the largest of the ascending branches. It arises from the second and third cervical nerves, winds around the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The Facial Branches pass across the parotid, and are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The Auricular Branches ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.
The Mastoid Branch communicates with the occipitalis minor and the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The Superficial Cervical Nerve or the Superficialis Colli (*n. cutaneus colli*) (Fig. 634).—The superficial cervical nerve or the superficialis colli arises from the second and third cervical nerves, turns around the posterior border of the Sterno-

mastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the anterior border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the antero-lateral parts of the neck.

The Ascending Branch or Branches (*rami superiores*) gives a filament which accompanies the external jugular vein; it then passes upward to the sub-maxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce
that muscle and are distributed to the integument of the upper half of the neck, at its forepart, as high as the chin.

The Descending Branches (rami inferiores), usually represented by two or more filaments, pierce the Platysma, and are distributed to the integument of the side and front of the neck, as low as the sternum.

The Descending or Supraclavicular Branches (nn. supraclaviculares) (Fig. 634).—The descending or supraclavicular branches arise from the third and fourth cervical nerves; emerging beneath the posterior border of the Sterno-mastoid, they descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

The Inner or Suprasternal Branches (nn. supraclaviculares anteriores) cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sterno-mastoid muscle, and supply the integument as far as the median line. They furnish one or two filaments to the sterno-clavicular joint. The Middle or Supraclavicular Branches (nn. supraclaviculares mediae) cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The External or Supra-acromial Branches (nn. supraclaviculares posteriores) pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

The Deep Branches of the Cervical Plexus (Fig. 635). Internal Series. The Communicating Branches.—The communicating branches consist of several filaments which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal, and sympathetic; of branches from all four cervical nerves to the superior cervical ganglion of the sympathetic, together with a branch from the fourth to the fifth cervical.

Muscular Branches.—Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The Communicantes Hypoglossi (Fig. 635).—The communicantes hypoglossi consist usually of two filaments, one being derived from the second and the other from the third cervical. These filaments pass downward on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels. Occasionally, the junction of these nerves takes place within the sheath.

The Phrenic or the Internal Respiratory Nerve of Bell (n. phrenicus) (Figs. 635 and 636).—The phrenic or the internal respiratory nerve of Bell arises chiefly from the fourth cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus muscle, and beneath the Sterno-mastoid muscle, the posterior belly of the Omohyoid muscle, and the Transversalis colli and suprascapular vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, some few of which are distributed to its thoracic surface, but most of which separately pierce that muscle and are distributed to its under surface (rami phrenicoabdominales).

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.
The right phrenic nerve is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and superior vena cava.

The left phrenic nerve is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. It enters the thorax behind the left innominate vein, and crosses in front of the vagus and the arch of the aorta and the root of the lung. In the thorax each phrenic nerve is accompanied by a branch of the internal mammary artery, the comes nervi phrenici.

Each nerve supplies filaments to the Diaphragm, pericardium, and pleura, and near the chest is joined by a filament from the sympathetic, and, occasionally, by one from the union of the descendens hypoglossi with the spinal nerves; this filament is found, according to Swan, only on the left side. The phrenic frequently receives a filament from the nerve to the Subclavian muscle. Branches have been described as passing to the peritoneum.

From the right nerve one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava.

From the left nerve filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.
Surgical Anatomy.—Irritation of the phrenic nerve causes hiccough and persistent cough. Bilateral paralysis of the phrenic causes death from paralysis of the Diaphragm. This form of death is seen by the surgeon in fracture-dislocation of the third cervical vertebra. Division of the phrenic on one side is not fatal, and is occasionally practised by the surgeon in removing a tumor of the neck. In Hearn's and Franklin's cases of removal of the pneumogastric, the phrenic was also divided. Unilateral division of the phrenic nerve causes paralysis of the corresponding half of the Diaphragm, which is difficult of recognition, because, as Gowers points out, the patient can still take deep inspirations, the thoracic muscles not being paralyzed.

The Deep Branches of the Cervical Plexus. External Series. Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the posterior triangle, and beneath the Trapezius.

Muscular Branches.—Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulae, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulae receive branches from the third and fourth.
The Scalenus medius is derived sometimes from the third, sometimes the fourth, and occasionally from both nerves.

**Surgical Anatomy.**—The cervical plexus may be damaged by wounds or contusions, which may or may not be associated with fracture of the clavicle. Paralysis ensues, the extent depending on the degree of damage. After a contusion the paralysis is apt to be temporary and to be followed by pain and muscular spasm in the arm. Paralysis of the arm due to plexus injury may be partial or complete. In some cases there is complete motor palsy and partial sensory palsy, the sensory impulses passing along undamaged collaterals. In certain spasmodic difficulties the surgeon occasionally stretches the cervical plexus. It is reached by an incision at the posterior margin of the Sterno-cleido-mastoid muscle. This incision begins two inches below the level of the tip of the mastoid and is carried downward for three inches.

**The Brachial Plexus (Plexus Brachialis)** (Figs. 637, 638, 639).

The brachial plexus is formed by the union of the anterior divisions of the four lower cervical and the greater part of the first dorsal nerves, receiving usually a fasciculus from the fourth cervical nerve, and frequently one from the second dorsal nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement: above the clavicle...
THE NERVOUS SYSTEM

Fig. 638.—The right brachial plexus (infraclavicular portion) in the axillary fossa, viewed from below and in front. The Pectoralis major and minor muscles have been in large part removed; their attachments have been reflected. (Spalteholz.)

Fig. 639.—Plan of the brachial plexus.
(pars supraclavicularis) the fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius external to the outer border of the Scalenus anticus muscle, are blended into three trunks—an upper one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and a lower one, formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, to compose the infraclavicular part of the plexus (pars infraclavicularis), each of the nerves forming the plexus unite together soon after their exit from the intervertebral foramina to form a common trunk.
these three trunks divides into two branches, an anterior and a posterior.¹ The anterior divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the outer cord of the brachial plexus (fasciculus lateralis). The anterior division of the lower trunk passes down on the inner side of the axillary artery in the middle of the axilla, and forms the inner cord of the brachial plexus (fasciculus medialis). The posterior divisions of all three trunks unite to form the posterior cord of the brachial plexus (fasciculus posterior), which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the upper trunk prior to its junction with the posterior division of the lower and middle trunks. The posterior cord divides into the circumflex and musculo-spiral nerves.

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth cervical nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle; the fifth and sixth cervical nerves are joined by filaments to the middle cervical ganglion of the sympathetic, the seventh and eighth cervical to its inferior ganglion, and the first dorsal nerve to its first thoracic ganglion. Close to their exit from the intervertebral foramina the nerves give off the filaments to the ganglia.

¹ The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.—Ed. of 15th English edition.

**Fig. 642.**—Cutaneous nerves of the upper limb, ventral aspect. (W. Keiller, in Gerrish's Text-book of Anatomy.)

**Relations.**—In the neck, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the posterior belly
of the Omo-hyoid muscle and by the transversalis colli artery. When the posterior scapular artery arises from the third part of the subclavian it usually passes between the roots of the plexus. The plexus lies at first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery; it next passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. It is in close relation with the apex of the lung (Luschka). **In the axilla** it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

**Branches.**—The branches of the brachial plexus are arranged in two groups—viz., those given off **above the clavicle**, and those below the clavicle.

**Branches above the Clavicle** (Figs. 637 and 639).—The branches above the clavicle, from the pars supraclavicularis, are—the

Communicating.
Muscular.
Posterior thoracic.
Suprascapular.

**The Communicating Branch** (Figs. 636 and 639).—The communicating branch with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle. The communications with the sympathetic have already been referred to.

**The Muscular Branches** (rami musculares).—The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the four lower cervical nerves at their exit.
from the intervertebral foramina. The Rhomboid branch is called the posterior scapular nerve (n. dorsalis scapulae) (Figs. 637 and 639), arises from the fifth
The Brachial Plexus

983
cervical, pierces the Scalenus medius, and passes beneath the Levator anguli
scapulae, which it occasionally supplies, to the Rhomboid muscles. The nerve to
the Subclavius (n. subclavius) is a small filament which arises from the fifth cervical
at its point of junction with the sixth nerve; it descends in front of the third
part of the subclavian artery to the Subclavius muscle, and is usually connected
by a filament with the phrenic nerve.

The Posterior Thoracic, the Long Thoracic, or the External Respiratory Nerve of Bell
(n. thoracialis longus) (Figs. 637, 638, 639, and 644).—The posterior thoracic, the
long thoracic, or the external respiratory nerve of Bell supplies the Serratus
magnus muscle, and is remarkable for the length of its course. It sometimes
arises by two roots from the fifth and sixth cervical nerves immediately after
their exit from the intervertebral foramina, but generally by three roots from
the fifth, sixth, and seventh nerves. These unite in the substance of the Middle
scalenum muscle, and, after emerging from it, the nerve passes down behind the
brachial plexus and the axillary vessels, resting on the outer surface of the Serratus
magnus. It extends along the side of the chest to the lower border of that muscle,
supplying filaments to each of the muscular digitations.

The Suprascapular Nerve (n. suprascapularis) (Figs. 637, 639, and 645).—The
suprascapular nerve arises from the cord formed by the fifth and sixth cervical
nerves; passing obliquely outward beneath the Trapezius and the Omo-hyoid, it
enters the supraspinous fossa below the transverse or suprascapular ligament,
and, passing beneath the Suprascapulator muscle, curves around the external border
of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa
it gives off two branches to the Suprascapulator muscle, and an articular fila-
ment to the shoulder-joint; and in the infraspinous fossa it gives off two branches
to the Infraspinatus muscle, besides some filaments to the shoulder-joint and
scapula.

Branches below the Clavicle (Figs. 638 and 639).—The branches below the clavicle, that is, the branches from the pars subclavicularis of the brachial
plexus, are derived from the three cords of the brachial plexus, in the following
manner:

From the Outer Cord.—From the outer cord arise the external anterior thoracic
nerve, the musculo-cutaneous, and the outer head of the median.

From the Inner Cord.—From the inner cord arise the internal anterior thoracic
nerve, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg),
the ulnar, and inner head of the median.

From the Posterior Cord.—From the posterior cord arise two of the three sub-
scapular nerves, the third taking origin from the posterior division of the trunk
formed by the fifth and sixth cervical nerves; the cord then divides into the
musculo-spiral and circumflex nerves.

These branches from below the clavicle may be arranged according to the
parts they supply:

To the chest . . . . Anterior thoracic.

To the shoulder . . . .

| Subscapular. |
| Circumflex. |

| Musculo-cutaneous. |
| Internal cutaneous. |
| Lesser internal cutaneous. |
| Median. |
| Ulnar. |
| Musculo-spiral. |
The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

- **External anterior thoracic** from 5th, 6th, and 7th cervical.
- **Internal anterior thoracic** from 8th cervical and 1st dorsal.
- **Subscapular** from 5th, 6th, 7th, and 8th cervical.
- **Circumflex** from 5th and 6th cervical.
- **Musculo-cutaneous** from 5th and 6th cervical.
- **Internal cutaneous** from 8th cervical and 1st dorsal.
- **Lesser internal cutaneous** from 1st dorsal.
- **Median** from 6th, 7th, and 8th cervical, and 1st dorsal.
- **Ulnar** from 8th cervical and 1st dorsal.
- **Musculo-spiral** from 6th, 7th, and 8th cervical, sometimes also from the 5th.

**The Anterior Thoracic Nerves (nn. thoracales anteriores)** (Figs. 637, 638, and 639).—The anterior thoracic nerves, two in number, supply the Pectoral muscles.

The **External or Superficial Anterior Thoracic Nerve** (Figs. 637 and 644), the larger of the two, **arises** from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major muscle. It sends down a communicating filament to join the internal anterior thoracic nerve, and this communicating filament forms a loop around the inner side of the axillary artery.

The **Internal or Deep Anterior Thoracic Nerve** **arises** from the inner cord, and through it from the eighth cervical and first dorsal nerves. It passes behind the first part of the axillary artery, then curves forward between the axillary artery and vein, and joins with the filament from the anterior nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some two or three branches pass through the muscle and reach the Pectoralis major.

**The Subscapular Nerves (nn. subscapulares)** (Figs. 638 and 639).—The subscapular nerves **arise** from the posterior cord of the plexus. There are three subscapular nerves, and they supply the Subscapularis, Teres major, and Latissimus dorsi muscles, and give filaments to the shoulder-joint. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The **First, Short or Upper Subscapular Nerve**, the smallest, **arises** from the posterior division of the upper trunk of origin of the brachial plexus, and enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The **Second or Lower Subscapular Nerve** arises from the posterior end of the brachial plexus, enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The **Third, Middle or Long Subscapular Nerve (n. thoracodorsalis)** (Fig. 638), the largest of the three, **arises** from the posterior end of the brachial plexus and follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi muscle, through which it may be traced as far as its lower border.

**The Circumflex Nerve (n. axillaris)** (Figs. 639 and 645).—The circumflex nerve supplies some of the muscles, the shoulder-joint, and the integument of the shoulder (Figs. 640 and 641). It **arises** from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downward
and outward to the lower border of that muscle. It then winds backward in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Teres minor muscle, below by the Teres major muscle, internally by the long head of the Triceps muscle, and externally by the neck of the humerus. The nerve then divides into two branches.

The Upper Branch (Fig. 645) winds backward around the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part (Fig. 642).

The Lower Branch (Fig. 645), at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filaments to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid (n. cutaneus brachii lateralis), as well as that covering the long head of the Triceps (caput longum n. tricipitis brachii) (Fig. 643).

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis muscle.

The Musculo-cutaneous or the External Cutaneous Nerve or the Perforating Nerve of Casserius¹ (n. musculocutaneus) (Figs. 638, 639, and 644).—The musculo-cutaneous, or the external cutaneous nerve, supplies some of the muscles of the arm and the integument of the forearm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor muscle, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coraco-brachialis muscle (Fig. 644), passes obliquely between the Biceps and Brachialis anticus muscles to the outer side of the arm, and, a little above the elbow, winds around the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous (Fig. 640). This nerve, in its course through the arm, supplies the Coraco-brachialis, Biceps, and the greater part of the Brachialis anticus muscles. The branch to the Coraco-brachialis is given off from the nerve close to its origin, and in some instances, as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coraco-brachialis. The nerve also sends a small branch to the humerus, which enters the nutrient foramen with the accompanying artery, and a filament, from the branch supplying the Brachialis anticus, goes to the elbow-joint. The musculo-cutaneous furnishes the chief nerve supply to this joint.

The Cutaneous Portion of the Musculo-cutaneous Nerve (n. cutaneus antibrachii lateralis) passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The anterior branch descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and with the palmar cutaneous branch of the median.

The posterior branch passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral. The cutaneous areas supplied by the musculo-cutaneous nerve are indicated in Figs. 642 and 643.

The musculo-cutaneous nerve presents frequent irregularities. It may adhere

¹ See foot-note, page 1027.
for some distance to the median and then pass outward, beneath the Biceps, instead of through the Coraco-brachialis. Frequently some of the fibres of the median run for some distance in the musculo-cutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to join the musculo-cutaneous. Instead of piercing the Coraco-brachialis muscle the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator radii teres muscle, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The Internal Cutaneous Nerve (n. cutaneus antibrachii medialis) (Figs. 638, 639, and 644).—The internal cutaneous nerve is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar nerve and internal head of the median nerve, and, at its commencement, is placed on the inner side of the axillary artery, and afterward on the brachial artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The anterior branch, the larger of the two, passes usually in front of, but occasion¬ally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve (Fig. 640).

The posterior branch passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument (Fig. 641). It communicates, above the elbow, with the lesser internal cutaneous nerve, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan). The cutaneous areas supplied by the internal cutaneous nerve are indicated in Figs. 642 and 643.

The Lesser Internal Cutaneous Nerve or the Nerve of Wrisberg (n. cutaneus brachii medialis) (Figs. 638, 639, and 644).—The lesser internal cutaneous nerve is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of, the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow (Figs. 640, 641, and 642), where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and the intercosto-humeral nerve are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which filament represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely by the intercosto-humeral.

The Median Nerve (n. medianus) (Figs. 638, 639, and 644).—The median nerve has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and musculo-spiral nerves, and the ulnar and
the radial nerves. It arises by two roots, one from the outer, and one from the inner, cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. The median nerve receives filaments from the sixth, seventh, and eighth cervical and the first dorsal nerves. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus muscle. In the forearm it passes between the two heads of the Pronator radii teres muscle, and descends beneath the Flexor sublimis muscle, lying on the Flexor profundus muscle, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis muscles, beneath, and rather to the radial side or under the tendon of the Palmaris longus, covered by the integument and fascia. It then passes through the carpal canal (canalis carpi) beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a branch of the anterior interosseous artery.

Branches.—With the exception of the nerve to the Pronator radii teres muscle, which sometimes arises above the elbow-joint, and filaments to the elbow-joint, the median nerve gives off no branches in the arm. In the forearm its branches are muscular, anterior interosseous, and palmar cutaneous, and, according to Rüdinger and Macalister, two articular twigs to the elbow-joint.

The Muscular Branches (rami musculares) supply all the superficial muscles on the front of the forearm except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow.

The Anterior Interosseous (n. interosseus [antibrachii] volaris) (Fig. 644) supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus muscle sending filaments to the inferior radio-ulnar articulation and the wrist-joint.

The Palmar Cutaneous Branch (ramus cutaneus palmaris n. mediani) arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the outer branch supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the inner branch supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and is crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the external branch supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the internal branch supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers. The digital branches, before they subdivide, are called common palmar digital branches of the median nerve (nn. digitales volares communes).

The branch to the muscles of the thumb (ramus muscularis) is a short nerve which divides to supply the Abductor, Opponens, and the superficial head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The Collateral Palmar Digital or the Digital Branches (nn. digitales volares proprii) are five in number. The first and second pass along the borders of the thumb,
the external branch communicating with branches of the radial nerve. The third
passes along the radial side of the index finger, and supplies the First lumbricalis
muscle. The fourth subdivides to supply the adjacent sides of the index and
middle fingers, and sends a branch to the Second lumbricalis muscle. The fifth
supplies the adjacent sides of the middle and ring fingers, and communicates with
a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal
branch, which joins the dorsal digital nerve from the radial nerve and runs along
the side of the dorsum of the finger, to end in the integument over the last phalanx.
At the end of the finger the digital nerve divides into a palmar and a dorsal branch,
the former of which supplies the extremity of the finger, and the latter ramifies
around and beneath the nail. The digital nerves, as they run along the fingers, are
placed superficial to the digital arteries. The cutaneous areas supplied by the
median nerve are shown in Figs. 642 and 643.

The Ulnar Nerve (n. ulnaris) (Figs. 638, 639, and 644).—The ulnar nerve is
placed along the inner or ulnar side of the upper limb, and is distributed to the
muscles and integument of the forearm and hand. It is smaller than the median,
behind which it is placed, diverging from it in its course down the arm. It arises
from the inner cord of the brachial plexus, in common with the inner head of the
median and the internal cutaneous nerve, and derives its fibres from the eighth
cervical and first dorsal nerves. At its commencement it lies to the inner side of
the axillary artery, and holds the same relation with the brachial artery to the
middle of the arm. From this point it runs obliquely across the internal head of
the Triceps, pierces the internal intermuscular septum, and descends to the
groove between the internal condyle and the olecranon, accompanied by the in-
ferior profunda artery. At the elbow it rests upon the back of the inner condyle,
and passes into the forearm between the two heads of the Flexor carpi ulnaris
muscle. In the forearm it descends in a perfectly straight course along the ulnar
side of the extremity, lying upon the Flexor profundus digitorum muscle, its upper
half being covered by the Flexor carpi ulnaris muscle, its lower half lying
on the outer side of the muscle, being covered by the integument and fascia.
The ulnar artery, in the upper third of its course, is separated from the ulnar
nerve by a considerable interval, but in the rest of its extent the nerve lies to
its inner side. At the wrist the ulnar nerve crosses the annular ligament on the
outer side of the pisiform bone, to the inner side of and a little behind the ulnar
artery, and immediately beyond this bone divides into two branches, the
superficial and the deep palmar.

Branches.—The branches of the ulnar nerve are—

In the forearm

| Articular. |
| Muscular. |
| Cutaneous. |

In the hand

| Superficial palmar. |
| Deep palmar. |

The Articular Branches distributed to the elbow-joint consist of several small
filaments. They arise from the nerve as it lies in the groove between the inner
condyle of the humerus and the olecranon process of the ulnar.

The Muscular Branches (rami musculares) are two in number—one supplying
the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digi-
torum. They arise from the trunk of the nerve near the elbow.

The Cutaneous Branch arises from the ulnar nerve about the middle of the fore-
arm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is
distributed to the integument, communicating with a branch of the internal
cutaneous nerve.

The second branch, the palmar cutaneous (ramus cutaneus palmaris) lies on the
ulnar artery, which it accompanies to the hand, some filaments entwining around the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The Dorsal Cutaneous Branch (ramus dorsalis manus) arises about two inches above the wrist; it passes backward beneath the Flexor carpi ulnaris muscle, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches (nn. digitales dorsales); one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying these parts; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the palmar digital branches of the ulnar.

The Superficial Palmar Branch (ramus superficialis n. ulnaris) supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The Deep Palmar Branch (ramus profundus n. ulnaris), accompanied by the deep branch of the ulnar artery, passes between the Abductor and Flexor brevis minimi digiti muscles; it then perforates the Opponens minimi digiti and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger, it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint, and to the bones and joints of the hand.

It will be remembered that the inner part of the Flexor profundus digitorum muscle is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscles, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar. The palmar branches of the ulnar which go to the fingers are called by Toldt before division common palmar digital branches, and after division collateral palmar digital branches. The cutaneous areas supplied by the ulnar nerve are shown in Figs. 642 and 643.

The Musculo-spiral Nerve (n. radialis) (Figs. 639, 644, and 645).—The musculo-spiral nerve, the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand (Figs. 642 and 643). It arises from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. It receives filaments from the sixth, seventh, and eighth, and sometimes also from the fifth cervical nerves. At its commencement it is placed behind the axillary artery and the upper part of the brachial artery, passing down in front of the tendons of the Latissimus dorsi and Teres major muscles. It winds around the humerus in the musculo-spiral
groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle (Fig. 645). It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus muscles to the front of the external condyle of the humerus, where it sends filaments to the elbow-joint and divides into the radial and posterior interosseous nerves.

**Branches.**—The branches of the musculo-spiral nerve are—

- **Muscular.**
- **Cutaneous.**
- **Radial.**
- **Posterior interosseous.**

The **Muscular Branches** (rami musculares n. radialis) are divided into internal, posterior, and external; they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus muscles. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.

The **internal muscular branches** supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is therefore frequently spoken of as the ulnar collateral branch.

The **posterior muscular branch**, of large size, arises from the nerve in the groove between the Triceps muscle and the humerus. It divides into branches which supply the outer and inner heads of the Triceps and the Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The **external muscular branches** supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus muscles.

The **Cutaneous Branches** are three in number, one internal and two external.

The **internal cutaneous branch** (n. cutaneus brachii posterior) arises in the axillary space with the inner muscular branch. It is of small size, and passes through
the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral nerve, with which it communicates.

The external cutaneous branch (n. cutaneus antibrachii dorsalis) divides into two branches, and each one perforates the outer head of the Triceps muscle at its attachment to the humerus. The upper and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The lower branch pierces the deep fascia below the insertion of the Deltoid muscle, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The Radial Nerve (ramus superficialis n. radialis) (Fig. 644), passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus muscle. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It leaves the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus muscle, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into four digital nerves (nn. digitales dorsales), which are distributed as follows: The first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.³ The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The Posterior Intercosseous Nerve (ramus profundus n. radialis) (Figs. 644 and 645).—The posterior interosseous nerve winds to the back of the forearm around the outer side of the radius, passes between the two planes of fibres of the Supinator brevis muscle, and is prolonged downward between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis muscle, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the inferior radio-ulnar articulation, to the wrist-joint, and to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

Surgical Anatomy.—The brachial plexus may be ruptured by traction on the limb, leading to complete paralysis. Bristow⁴ has reported three cases of avulsion of the plexus and has described twenty-four cases. In these cases it is generally believed that the lesion is rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In a case operated upon by Bristow it was found that the plexus had given way where the four cervical nerves and the first dorsal nerve unite to form three trunks. In supraclavicular division of the brachial plexus, not only will there be motor and sensory paralysis in the limb, but the Serratus magnus muscle will probably be paralyzed, because of injury to the posterior thoracic nerve. In the axilla any of the nerves forming the brachial plexus may be injured by a wound of this part, the one which is most frequently damaged from its exposed

³ According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx, and the one to the middle and ring fingers not higher than the first phalangeal joint (Lond. Hospital Gazette, vol. iii. p. 319).—Ed. of 15th English edition, Annals of Surgery, September, 1902.
position. The musculo-spiral, on account of its sheltered and deep position, is least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as crutch paralysis. In these cases the musculo-spiral is the nerve most frequently implicated; the ulnar nerve being the one that appears to suffer next in frequency.

The circumflex nerve is of particular surgical interest. On account of its course around the surgical neck of the humerus, it is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles which move that joint.

The median nerve is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers can still be effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation is limited to the back of the last phalanx. In order to expose the median nerve for the purpose of stretching it an incision should be made along the radial side of the tendon of the Palmaris longus muscle, which serves as a guide to the nerve.

The ulnar nerve is liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction of the hand; there is inability to spread out the fingers from paralysis of the Interossei; and there is inability to adduct the thumb. The fingers cannot be flexed at the first joints, and cannot be extended at the other joints. A claw-hand develops, the first phalanges being overextended and the others flexed. Sensation is lost or impaired in the skin of the ulnar side of the hand anteriorly and posteriorly, involving the little finger, the ring finger, and the ulnar half of the middle finger posteriorly, and anteriorly involving the little finger and the ulnar half of the ring finger. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The musculo-spiral nerve is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be squeezed against the bone by kicks or blows and it may be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This condition is known as drop-wrist. The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the Interossei, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm is flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps. Loss of sensation may be considerable or slight. Its area is shown in Fig. 643. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the Supinator longus muscle, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Supinator longus the nerve will be found lying beneath it, on the Brachialis anticus muscle.

Post-anaesthetic paralysis. When a person emerges from the influence of a general anaesthetic palsy of the arm may be found to exist. The brachial plexus may have been compressed during the operation by drawing the arm strongly from the body or elevating it by the side of the head. In such a case the plexus was compressed by the head of the humerus (Braun).

The median nerve is stretched when the arm is rotated externally and drawn backward and outward. The ulnar nerve is stretched when the forearm is flexed and supinated (Braun). Garrigues believes that in most cases of post-anaesthetic paralysis the brachial plexus was squeezed between the collar bone and the first rib by the head of the patient being drawn to the opposite side or being allowed to fall back.
THE THORACIC OR DORSAL NERVES (NN. THORACALES.)

The thoracic or dorsal nerves are twelve in number on each side. The first appears between the first and second dorsal vertebrae, and the last between the last dorsal and first lumbar.

The Roots of the Thoracic or Dorsal Nerves.

The roots of the thoracic or dorsal nerves are of small size, and vary but slightly from the second to the last. Both roots are very slender, the posterior roots slightly exceeding the anterior in thickness. They gradually increase in length from above downward, and in the lower part of the dorsal region pass down in contact with the spinal cord for a distance equal to the height of at least two vertebrae, before they emerge from the spinal canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The Posterior Divisions of the Thoracic or Dorsal Nerves (Rami Posteriores) (Fig. 646).

The posterior divisions of the thoracic or dorsal nerves are smaller than the anterior, pass backward between the transverse processes, and divide into internal and external branches.

Each internal branch is called a ramus medialis; each external branch is called a ramus lateralis.

The Internal Branches.—The internal branches of the six upper nerves pass inward between the Semispinalis dorsi and Multifidus spinææ muscles, which they supply, and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the Multifidus spinææ, without giving off any cutaneous filaments.

The External Branches.—The external branches increase in size from above downward. They pass through the Longissimus dorsi muscle to the cellular interval between it and the Iliocostalis muscle, and supply those muscles, as well as their continuations upward to the head, and also the Levatores costarum muscles; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Cutaneous Branches.—The cutaneous branches of the posterior primary divisions of the dorsal nerves are twelve in number. From each ramus medialis of the upper six nerves comes a ramus cutaneus medialis, and from each ramus lateralis of the lower six nerves comes a ramus cutaneus lateralis. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Anterior Divisions of the Thoracic or Dorsal Nerves or the Intercostal Nerves (Rami Anteriores).

The anterior divisions of the dorsal nerves or the intercostal nerves (nn. intercostales) are twelve in number on each side. They are, for the most part,
distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the
other spinal nerves. Each nerve is connected with the adjoining ganglion of the sympathetic by one or two filaments (ramus communicans). The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the buttock.

The Anterior Division of the First Thoracic or First Dorsal Nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the first intercostal nerve (n. intercostalis I), giving off muscular branches, and terminates on the front of the chest by forming the first anterior cutaneous nerve (ramus cutaneus anterior n. intercostalis I) of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercosto-humeral. It frequently receives a connecting twig from the second dorsal nerve, which passes upward over the neck of the second rib.

The Anterior Divisions of the Upper Thoracic or Dorsal Nerves (nn. intercostales) (Fig. 646).—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are confined to the parietes of the thorax, and are named upper or pectoral intercostal nerves. They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membrane, and Pectoralis major muscle, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax; the branch from the second nerve is joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments (rami musculares) supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posterior superior, and Triangularis sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.

Lateral Cutaneous Nerves of the Thorax (rami cutanei laterales [pectoralis]) (Fig. 638).—These are derived from the intercostal nerves, midway between the vertebrae and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, anterior and posterior.

The Anterior Branches (rami anteriores) are reflected forward to the side and the forepart of the chest, supplying the integument of the chest and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique muscle.

The Posterior Branches (rami posteriores) are reflected backward to supply the integument over the scapula and over the Latissimus dorsi muscle.

The Lateral Cutaneous Branch of the Second Intercostal Nerve (n. intercosto-brachialis) is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It may unite with a branch of the third intercostal. The single nerve or the united nerve is named, from its origin and distribution, the intercosto-humeral nerve (Figs. 638 and 644). It pierces the External intercostal
muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm (Figs. 642 and 643), communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm. It may or may not send a branch to the intercosto-humeral.

The Anterior Divisions of the Lower Thoracic or Dorsal Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, and the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named lower or abdominal intercostal nerves. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the anterior cutaneous nerves of the abdomen. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off lateral cutaneous branches which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed to the integument of the abdomen and back; the anterior branches supply the digitations of the External oblique muscle and extend downward and forward nearly as far as the margin of the Rectus muscle; the posterior branches pass backward to supply the skin over the Latissimus dorsi muscle.

The Last Thoracic or Dorsal Nerve.—The last dorsal is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib, and passes under the external arcuate ligament of the Diaphragm. It then runs in front of the Quadratus lumborum muscle, perforates the Transversalis muscle, and passes forward between it and the Internal oblique muscle, to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the dorsi-lumbar nerve, which descends in the substance of the Quadratus lumborum muscle. It gives a branch to the Pyramidalis muscle.

The Cutaneous Branches.—There are two cutaneous branches, an anterior and a lateral.

The Anterior Cutaneous Branch is a terminal branch and is a direct prolongation from the intercostal. It supplies an area of skin of the abdominal wall between the umbilicus and pubis.

The Lateral Cutaneous Branch (ramus cutaneus lateralis [abdominalis] intercostalis XII) is remarkable for its large size; it perforates the Internal and External oblique muscles, passes downward over the crest of the ilium in front of the iliac branch of the ilio-hypogastric, and is distributed to the integument of the front part of the gluteal region, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and a posterior branch, like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward
fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach;" the eighth corresponds to about the position of the middle line transversa; the tenth to the umbilicus; and theilio-hypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical significance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near their origin the pain is referred to their peripheral terminations. Thus in Pott's disease of the spine children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied around the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tubes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdominal wall supply also the muscles which constitute the greater part of the abdominal wall. Hence, it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin are derived from the lower intercostal nerves and are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in rupture of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBAR NERVES (NN. LUMBALES).

The lumbar nerves are five in number on each side. The first lumbar nerve appears between the first and second lumbar vertebrae, and the last between the last lumbar vertebra and the base of the sacrum.

The Roots of the Lumbar Nerves.

The roots of the lumbar nerves are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller, but there is not the same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, posterior and anterior.

The Posterior Divisions of the Lumbar Nerves (Rami Posteriore) (Fig. 646).

The posterior divisions of the lumbar nerves diminish in size from above downward; they pass backward between the transverse processes, and divide into internal and external branches.
The Internal Branches (rami mediales).—The internal branches, the smaller, pass inward close to the articular processes of the vertebrae, and supply the Multifidus spinae and Interspinales muscles.

The External Branches (rami laterales).—The external branches supply the Erector spinae and Intertransverse muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major (Fig. 652).

The posterior division of the fifth lumbar nerve usually sends a branch which forms a loop with the posterior division of the first sacral nerve.

The Anterior Divisions of the Lumbar Nerves (Rami Anteriores).

The anterior divisions of the lumbar nerves increase in size from above downward. At their origin they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries around the sides of the bodies of the vertebrae, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the five lumbar, five sacral, and first coccygeal nerve constitute the lumbo-sacral plexus (plexus lumbosacralis). This is subdivided into the lumbar plexus, the sacral plexus, and the pudendal plexus. The anterior divisions of the four upper nerves are connected together in this situation by anastomotic loops, and form the lumbar plexus. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the lumbo-sacral cord (truncus lumbosacralis) (Figs. 648 and 655).

The Lumbar Plexus (Plexus Lumbalis) (Figs. 647, 648).

The lumbar plexus is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last dorsal nerve by a slender branch, the dorsi-lumbar nerve. The plexus is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. The lumbar plexus is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse processes of the lumbar vertebrae.

The mode in which the plexus is arranged varies in different subjects. It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves in the following manner: The first lumbar nerve receives a branch from the last dorsal, and gives off a larger branch, which subdivides into the ilio-hypogastric and ilioinguinal nerves; the first lumbar also gives off a communicating branch which passes down to the second lumbar nerve, and a third branch which unites with a branch of the second lumbar, to form the genito-crural nerve. The second, third, and fourth lumbar nerves divide into anterior and posterior divisions. The anterior division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-crural; the other unites with the anterior division of the third nerve, and a part of the anterior division of the fourth nerve to form the obturator nerve. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerves divide into two
branches, a smaller branch from each uniting to form the **external cutaneous nerve**, and a larger branch from each, which join with the whole of the posterior division of the fourth lumbar nerve to form the **anterior crural**. The **accessory obturator**, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-crural from the first and second nerves; the external cutaneous from the second and third; the anterior crural and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

**Branches** (Figs. 647 and 648).—The branches of the lumbar plexus are—the

- Ilio-hypogastric.
- Ilio-inguinal.
- Genito-crural.
- External cutaneous.
- Obturator.
- Accessory obturator.
- Anterior crural.

**The Ilio-hypogastric Nerve** (*n. iliohypogastricus*) (Figs. 647 and 648).—The ilio-hypogastric nerve *arises* from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part near the crest of the ilium. It gives off **muscular branches** (*rami musculares*) to the abdominal wall, and divides between the transversalis and the Internal oblique into two cutaneous branches, **iliac** and **hypogastric**.

The **Iliac Branch** (*ramus cutaneus lateralis*) pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (Figs. 652 and 656). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The **Hypogastric Branch** (*ramus cutaneus anterior*) (Fig. 649) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region. The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

**The Ilio-inguinal Nerve** (*n. ilioinguinalis*) (Figs. 647, 648, and 649).—The ilio-inguinal nerve, smaller than the preceding, *arises* with it from the first lumbar nerve. It emerges from the outer border of the Psoas muscle just below the ilio-hypogastric nerve, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the forepart of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distribu-
ting muscular branches (rami musculares) to it, and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male (nn. scrotales anteriores) (Fig. 651), and to the labium majus in the female (nn. labiales anteriores). The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the ilio-inguinal nerve may be altogether absent.

The Genito-crural Nerve (n. genitofemoralis) (Figs. 647 and 648) arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas muscle, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebrae; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a genital and a crural branch.

The Genital Branch (n. spermaticus externus) passes outward on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; in the male it then descends along the back part of the spermatic cord to the scrotum, and supplies the Cremaster muscle. In the female it accompanies the round ligament, and is lost upon it.

The Crural Branch (n. lumboinguinalis) (Fig. 649) descends on the external iliac artery, sending a few filaments around it, and, passing beneath Poupart's ligament
Fig. 649.—Cutaneous nerves of lower extremity. Front view.

Fig. 650.—Nerves of the lower extremity. Front view.
to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee (Fig. 651). On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Pouchart’s ligament.
The External Cutaneous Nerve (n. cutaneus femoris lateralis) (Figs. 647, 648, 649, and 650).—The external cutaneous nerve arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, toward the anterior superior spine of the ilium. It then passes under Poupart’s ligament and over the Sartorius muscle into the thigh, where it divides into two branches, anterior and posterior.

The Anterior Branch descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart’s ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee (Fig. 651). This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The Posterior Branch pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the middle of the thigh (Fig. 652).

The Obturator Nerve (n. obturatorius) (Figs. 647, 648, and 650).—The obturator nerve supplies the Obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the second, the third, and the fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus muscle, and lower down by the Adductor brevis muscle.

The Anterior Branch (ramus anterior) (Fig. 650) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch (ramus cutaneus), to the thigh and leg. When this is so, this occasional cutaneous branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small its place is supplied by the internal cutaneous nerve.

The Posterior Branch (ramus posterior) pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. One of the branches gives off a filament to the knee-joint.

The Articular Branch for the Knee-joint is sometimes absent; it perforates the lower part of the Adductor magnus, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the popliteal artery in its course.
The Accessory Obturator Nerve or the Accessory Anterior Crural Nerve of Winslow (n. obturatorius accessorius) (Fig. 648).—The accessory obturator nerve is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally the articular branch is very small, and becomes lost in the capsule of the hip-joint.

The Anterior Crural Nerve (n. femoralis) (Figs. 647, 648, and 650).—The anterior crural nerve is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor fasciae latae; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot (Figs. 651 and 652); and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from muscle at the lower part of its outer border, and passes down between it and the Iliacus muscle, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart's ligament it is separated from the femoral artery by a portion of the Psoas muscle, and lies beneath the iliac fascia.

Within the abdomen the anterior crural nerve gives off from its outer side some small muscular branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies; it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

From the Anterior Division.  
Middle cutaneous. 
Internal cutaneous. 
Muscular. 

From the Posterior Division.  
Long saphenous. 
Muscular. 
Articular. 

The middle and internal cutaneous branches of the anterior crural nerve are the rami cutanei anteriores n. femoralis of the new nomenclature.

The Middle Cutaneous Nerve (Figs. 649 and 650) pierces the fascia lata (generally the Sartorius muscle also) about three inches below Poupart's ligament, and divides into two branches (Fig. 649), which descend in immediate proximity along the forepart of the thigh, to supply the integument as low as the front of the knee (Fig. 651), where it communicates with the internal cutaneous nerve and the patellar branch of the internal saphenous nerve, to form the patellar plexus. In the upper part of the thigh the outer division of the middle cutaneous nerve communicates with the crural branch of the genito-crural nerve.

The Internal Cutaneous Nerve (Fig. 649) passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, anterior and posterior or internal.

The anterior branch runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the nervus cutaneus patellae, a branch of the internal saphenous nerve.

The posterior or internal branch descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then
passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (Fig. 650). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh (Figs. 651 and 652). One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh (Fig. 649); and a third pierces the fascia at its lower third (Fig. 649).

The Muscular Branches of the Anterior Division (\textit{rami musculares}).—The \textit{nerve to the Pectineus} is often duplicated; it arises from the anterior crural immediately below Poupart's ligament, and passes inward behind the femoral sheath to enter the anterior surface of the muscle. The \textit{nerve to the Sartorius} arises in common with the middle cutaneous.

The \textbf{Long or Internal Saphenous Nerve} (\textit{n. saphenus}) (Figs. 649 and 650) is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Abductor magnus. It then leaves the artery, and descends vertically along the inner side of the knee, beneath the Sartorius muscle, pierces the fascia lata opposite the interval between the tendons of the Sartorius and Gracilis muscles, and becomes subcutaneous. The nerve then passes along the inner side of the leg (Fig. 649), accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

The long saphenous nerve \textbf{about the middle of the thigh} gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

At the \textbf{inner side of the knee} it gives off a large patellar branch, the \textit{nerve cutaneus patellae} (\textit{ramus infrapatellaris}), which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the \textit{patella plexus} (\textit{plexus patellae}). The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

\textbf{Below the knee} the branches of the long saphenous nerves are distributed to the integument of the front and inner side of the leg (Figs. 651 and 652), communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve. The nerve also sends filaments to the ankle-joint.

The \textbf{Muscular Branches of the Posterior Division}.—The muscular branches of the posterior division supply the four parts of the Quadriceps extensor muscle.

The \textit{branch to the Rectus muscle} enters its under surface high up, sending off a small filament to the hip-joint.

The \textit{branch to the Vastus externus muscle}, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.
The branch to the Vastus internus muscle is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

The branch to the Crureus muscle enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Subcrureus and the knee-joint.

The articular branch to the hip-joint is derived from the nerve to the Rectus muscle.

The articular branches to the knee-joint are three in number. One, a long, slender filament, is derived from the nerve to the Vastus externus muscle; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus muscle. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscle and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

THE SACRAL AND COCCYGEAL NERVES (NN. SACRALES ET COCCYGEUS).

The sacral nerves are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The Roots of the Upper Sacral Nerves.

The roots of the upper sacral nerves are the largest of all the spinal nerves; while those of the lowest sacral and the coccygeal nerve are the smallest. They are longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length, and the appearance they present in connection with their attachment to the spinal cord, the roots of origin of these nerves are called collectively the cauda equina.

Each sacral and coccygeal nerve separates into two divisions, posterior and anterior.

The Posterior Divisions of the Sacral Nerves (Rami Posteriores) (Fig. 653).

The posterior divisions of the sacral nerves are small, diminish in size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The Upper Sacral Nerves.—Each of the three upper ones is covered, at its exit from the sacral canal, by the Multifidus spinae muscle, and divides into an internal branch (ramus medialis) and an external branch (ramus lateralis).

The Internal Branches.—The internal branches are small, and supply the Multifidus spinae muscle.

The External Branches.—The external branches join with one another, and with the last lumbar and fourth sacral nerves, in the form of loops on the posterior surface of the sacrum, constituting the posterior sacral plexus. From these loops branches pass to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the Gluteus maximus muscle. Cutaneous branches from this second series of loops, usually two or three in number, pierce the Gluteus maximus muscle along a line drawn from the posterior superior spine
of the ilium to the tip of the coccyx. They supply the integument over the posterior part of the gluteal region (Fig. 652).

**The Lower Sacral Nerves.**—The posterior divisions of the two lower sacral nerves are situated below the Multifidus spinæ muscle. They are of small size, and do not divide into internal and external branches, but join with each other, and with the posterior division of the coccygeal nerve to form the **posterior sacro-coccygeal nerve**, which passes through the sacro-sciatic ligament, and forms loops on the back of the sacrum, filaments from which supply the Extensor coccygeus and the integument over the coccyx (Fig. 652).

**The Anterior Divisions of the Sacral Nerves (Rami Anteriores)** (Fig. 655).

The anterior divisions of the sacral nerves diminish in size from above downward. The four upper ones emerge from the anterior sacral foramina; the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forward between the sacrum and the coccyx. All the anterior sacral nerves at their exit from the sacral foramina communicate with the **sacral ganglia of the sympathetic**. The **first nerve** (Fig. 654), of large size, unites with the **lumbo-sacral cord (truncus lumbosacralis)**, formed by the fifth lumbar, and a branch from the fourth lumbar (n. furcalis). The **second** (Fig. 654), equal in size to the preceding, and the **third** (n. bigeminus) (Fig. 654), about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the **sacral plexus**, a visceral branch being given off from the third nerve to the bladder (Fig. 655).

The **Fourth Anterior Sacral Nerve** sends a branch to join the sacral plexus. The remaining portion of the nerve divides into **visceral** and **muscular branches**, and a communicating filament descends to join the fifth sacral nerve.
The visceral branches are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The visceral branches of the third and fourth sacral do not join the gangliated cord.

The muscular branches are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The Fifth Anterior Sacral Nerve, after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The Posterior Division of the Coccygeal Nerve.

The coccygeal nerve divides into its anterior and posterior divisions in the spinal canal. The posterior division is the smaller. It does not divide, but
receives, as already mentioned, a communicating branch from the last sacral, and is lost in the integument over the back of the coccyx.

**The Anterior Division of the Coccygeal Nerve.**

The anterior division of the coccygeal nerve is a delicate filament which escapes at the termination of the sacral canal; it passes downward behind the rudimentary transverse process of the first piece of the coccyx, and curves forward through the notch between the first and second pieces, piercing the Coccygeus muscle, and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

The **Pudendal Plexus** (*plexus pudendus*).—The pudendal plexus is formed by fibres obtained from the anterior divisions of the first three sacral nerves and by the anterior divisions of the two lower sacral nerves and the coccygeal nerve. It is, so to speak, interpolated in the sacral plexus and is considered as a portion of it.

**The Sacral or Sciatic Plexus (Plexus Sacralis) and the Pudic or Pudendal Plexus (Plexus Pudendalis)** (Fig. 655).

The sacral plexus is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves and a branch from the fourth. The pudic or pudendal plexus is considered with the sacral plexus. It is usually composed of the anterior divisions of the second, third, fourth, and fifth sacral nerves and the coccygeal nerve. It is irregular in composition. Prof. Cunningham says: "There is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the
THE NERVOUS SYSTEM

sacral plexus.” The nerves of these two plexuses proceed in different directions: the upper ones obliquely downward and outward, the lower ones nearly horizontally outward, and they all unite into two cords; an upper and larger cord, which is formed by the lumbo-sacral cord with the first, second, and the greater part of the third sacral nerves; and a lower and smaller cord, formed by the remainder of the third, with a portion of the fourth sacral nerve. The upper cord is prolonged into the great sciatic nerve and the lower into the pudic. Frequently a small filament is given off from the second sacral nerve to join the lower cord.

Each of the nerves which form the plexus joins the sympathetic by gray rami communicantes. White rami communicantes join the third sacral and sometimes also the second and fourth sacrals to the sympathetic.

The sacro-pudendal plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Pyriformis, and is covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis. The sacral plexus proper sends branches to the lower extremity; the pudendal plexus proper is largely limited to supplying the perineum.

Branches.—The branches of the sacro-pudendal plexus are divided into collateral and terminal branches.

The Muscular Branches (rami musculares).—The muscular branches supply the Pyriformis, Obturator internus, the two Gemelli, and the Quadratus femoris. The branch to the Pyriformis muscle arises from the upper two sacral nerves before they enter the plexus; the branch to the Obturator internus muscle arises at the junction of the lumbo-sacral and first sacral nerves; it passes out of the pelvis through the great sacro-sciatic foramen below the Pyriformis, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to enter the inner surface of the Obturator internus; the branch to the Gemellus superior muscle arises in common with the nerve to the Obturator internus muscle; it enters the muscle at the upper part of its posterior surface; the small branch to the Gemellus inferior and Quadratus femoris muscles also arises from the upper part of the plexus; it passes through the great sacro-sciatic foramen below the Pyriformis, and courses down beneath the great sciatic nerve, the Gemelli and tendon of the Obturator internus, supplies the muscles on their deep or anterior surface and gives off an articular branch to the hip-joint. A second articular branch is occasionally derived from the upper part of the sacral plexus.

The Superior Gluteal Nerve (n. gluteus superior) (Figs. 655 and 657).—The superior gluteal nerve arises from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve; it passes from the pelvis through the great sacro-sciatic foramen above the Pyriformis muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The Superior Branch follows the line of origin of the Gluteus minimus, and supplies the Gluteus medius muscle.

The Inferior Branch crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor fasciae femoris muscle, extending nearly to its lower end.
The Inferior Gluteal Nerve (n. gluteus inferior) (Fig. 655).—The inferior gluteal nerve arises from the lumbo-sacral cord and first and second sacral nerves, and is intimately connected with the small sciatic at its origin. It passes out of the pelvis through the greater sciatic notch beneath the Pyriformis muscle, and, dividing into a number of branches, enters the Gluteus maximus muscle on its under surface.

The Small Sciatic Nerve (n. cutaneus femoris posterior) (Figs. 655, 656, and 657).—The small sciatic nerve supplies the integument of the perineum and back part of the thigh and leg. It is usually formed by the union of two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata and over the long head of the Biceps, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The Branches of the small sciatic nerve are all cutaneous, and are grouped as follows: gluteal, perineal, and femoral.

The Gluteal Cutaneous Branches (nn. clunium inferiores [laterales]) consist of two or three ascending filaments, which turn upward around the lower border of the Gluteus maximus to supply the integument covering the lower and outer part of that muscle (Fig. 652).

The Perineal Cutaneous Branches (rami perineales) are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the inferior pudendal or long scrotal nerve (Fig. 657), curves forward below the tuber ischii, pierces the fascia lata, and passes forward beneath the superficial fascia of the perineum to be distributed to the integument of the scrotum in the male (Fig. 652) and the labium in the female, communicating with the superficial perineal and inferior hemorrhoidal nerves.

The Femoral Cutaneous Branches are numerous descending filaments, derived from both sides of the nerves, which are distributed to the back, inner, and outer sides of the thigh, to the skin covering the popliteal space, and to the upper part of the leg (Fig. 652).

The Perforating Cutaneous Nerve (n. clunium inferior medialis) (Fig. 655).—The perforating cutaneous nerve usually arises from the second and third sacral nerves, and is of small size. It is continued backward through the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the integument covering the inner and lower part of that muscle.

The Pudic Nerve (n. pudendus) (Figs. 655 and 657).—The pudic nerve is the direct continuation of the lower cord of the sacral plexus, and derives its fibres from the third and fourth sacral nerves, and frequently from the second also. It leaves the pelvis through the great sacro-sciatic foramen, below the Pyriformis. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, termed Alcock's canal, and divides into two terminal branches, the perineal nerve and the dorsal nerve of the penis or clitoris. Before its division it gives off the inferior hemorrhoidal nerve.

The Inferior Haemorrhoidal Nerve (n. haemorrhoidalis inferior) is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument around the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the forepart of the perineum.
THE NERVOUS SYSTEM

Fig. 656.—Cutaneous nerves of lower extremity. Posterior view.

N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

Fig. 657.—Nerves of the lower extremity.¹

Posterior view.

¹ N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.
The **Perineal Nerve** (*n. perinei*), the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into **cutaneous** and **muscular branches**.

The **cutaneous branches** (superficial perineal) are two in number, **posterior** and **anterior**. The **posterior** or **external branch** pierces the base of the triangular ligament of the urethra, and passes forward along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the skin of the scrotum (*nn. scrotales posteriores*). It communicates with the inferior haemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The **anterior** or **internal branch** also pierces the base of the triangular ligament, and passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The **muscular branches** are distributed to the Transversus perinacii, Accelerator urinae, Erector penis, and Compressor urethrae. A distant branch is given off from the nerve to the Accelerator urinae, which pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the **nerve to the bulb**.

The **Dorsal Nerve of the Penis** (*n. dorsalis penis*) is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; it then runs forward along the inner margin of the ramus of the os pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer it gives a branch to the corpus cavernosum, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans, to which it is distributed.

In the female the dorsal nerve is very small, and supplies the **clitoris** (*n. dorsalis clitoridis*).

The **Great Sciatic Nerve** (*n. ischiadicus*) (Figs. 655 and 657).—The great sciatic nerve supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the direct continuation of the upper division of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh, to about its lower third, where it divides into two large branches, the **internal and external popliteal nerves** (Fig. 657).

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus, the two nerves descend together side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the Pyriformis muscle. As the nerve descends along the back of the thigh, it rests upon the posterior surface of the ischium, the nerve of the Quadratus femoris, and the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps. The great sciatic even when apparently a single nerve is really two nerves appearing as one.

**Branches.**—The branches of the nerve, before its division, are **articular** and **muscular**.

The **Articular Branches** (*rami articulares*) arise from the upper part of the nerve; they supply the hip-joint, perforating the posterior part of its fibrous capsule. These branches are sometimes derived from the sacral plexus.

The **Muscular Branches** (*rami musculares*) are distributed to the flexors of the leg—viz., the Biceps, Semitendinosus, and Semimembranosus, and a branch goes to the Adductor magnus. These branches are given off beneath the Biceps muscle.
The Internal Popliteal or Tibial Nerve (n. tibialis) (Figs. 655 and 657), in reality, arises from the fourth and fifth lumbar nerves and the first three sacral nerves, and becomes a part of the trunk of the great sciatic in the buttock, to emerge from it again at the bifurcation of the sciatic. It is the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius muscle.

The branches of this nerve are—articular, muscular, and a cutaneous branch, the communicating tibial nerve.

The articular branches (rami articulares), usually three in number, supply the knee-joint; two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygos articular artery.

The muscular branches (rami musculares), four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, and the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn around its lower border and are distributed to its deep surface.

The tibial communicating nerve (n. cutaneus surae medialis) is the cutaneous branch. It descends between the two heads of the Gastrocnemius muscle, and about the middle of the back of the leg pierces the deep fascia, and joins the peroneal or fibular communicating nerve (ramus anastomoticus peroneaeus) from the external popliteal nerve to form the external or short saphenous (n. suralis) (Fig. 657). The external saphenous nerve, formed by the communicating branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It divides in two branches, the posterior of which breaks up into external calcaneal branches (rami calcanei laterales). The anterior branch (n. cutaneus dorsalis lateralis) winds around the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic. The cutaneous area supplied by the external saphenous nerve is indicated in Figs. 651, 652, and 659.

The Posterior Tibial Nerve (Fig. 657) is the terminal portion of the internal popliteal nerve. It commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the external and internal plantar nerves. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The branches of the posterior tibial nerve are muscular, internal calcaneal or calcaneo-plantar, and articular.

The muscular branches (rami musculares) arise either separately or by a common trunk from the upper part of the nerve. They supply the Soleus, Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the latter muscle accompanying the peroneal artery. The branch to the Soleus enters its deep surface, while the branch which this muscle receives from the internal popliteal enters its superficial aspect.
The **internal calcaneal** or **calcaneo-plantar branches** (*rami calcanei mediales*) perforate the internal annular ligament, and supply the integument of the heel and inner side of the foot (Fig. 659).

The **articular branch** (*ramus articularis ad articulationem talocruralem*) is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **Internal Plantar Nerve** (*n. plantaris medialis*) (Fig. 658), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and divides into the **common plantar digital nerves** (*nn. digitales plantares communes*), which pass forward between the Abductor hallucis and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into **four collateral plantar digital branches**, and communicates with the external plantar nerve.

In its course the internal plantar nerve gives off **cutaneous branches**, which pierce the plantar fascia and supply the integument of the sole of the foot (Fig. 659); **muscular branches**, which supply the Abductor hallucis and Flexor brevis digitorum; **articular branches**, to the articulations of the tarsus and metatarsus; and **four collateral plantar digital branches** (*nn. digitales plantares proprii*). The three outer branches pass between the divisions of the plantar fascia in the clefts between the toes; the first (innermost) branch becomes cutaneous farther back between the Adductor hallucis and Flexor brevis digitorum. They are distributed in the following manner: The **first** supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the **second** bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the **third** supplies the adjacent sides of the second and third toes; the **fourth** supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve (Fig. 659). Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve...
being distributed to the ball of the toe. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The External Plantar Nerve (n. plantaris lateralis) (Fig. 658), the smaller of the two, completes the nervous supply to the structures of the sole of the foot (Fig. 659), being distributed to the little toe, and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Abductor minimi digiti divides into a superficial and a deep branch. Before its division it supplies the Flexor accessorius and Abductor minimi digiti.

The superficial branch (ramus superficialis) separates into two digital nerves. Before division they are called common plantar digital nerves (nn. digitales plantares communes), after division the collateral plantar digital nerves (nn. digitales plantares proprii): one, the external branch, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The deep or muscular branch (ramus profundus) accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The External Popliteal or Peroneal Nerve (n. peroneaeus communis) (Figs. 655 and 657) in reality arises from the fourth and fifth lumbar and the first and second sacral nerves. It is about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds around the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the anterior tibial and musculo-cutaneous nerves.

The branches of the peroneal nerve, previous to its division, are articular and cutaneous.

The articular branches (rami artica res) are three in number: two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (recurrent) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The Sural or Lateral Cutaneous Branch (n. cutaneus surae lateralis).—There may be two or three of these branches. They supply the integument along the back part and outer side of the leg (Fig. 652). The largest cutaneous branch of the peroneal is the peroneal communicating (ramus anastomoticus peroneaeus or communicaeus fibularis), arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans tibialis to form the external sapheneus. This nerve occasionally exists as a separate branch, which is continued as far down as the heel.

The Anterior Tibial Nerve (n. peroneaeus profundus) (Fig. 650) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus muscle, passes obliquely forward beneath the Extensor longus digitorum muscle to the forepart of the interosseous membrane, and gets into relation with the anterior tibial artery above the middle of the leg; it then descends with
the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The branches of the anterior tibial nerve in its course through the leg are the muscular branches (rami musculares) to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an articular branch to the ankle-joint.

The external or tarsal branch of the anterior tibial passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum muscle. From the enlargement three minute interosseous branches are given off which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The internal branch, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two dorsal digital branches (nn. digitales dorsales hallucis lateralis et digitii secundi medialis), which supply the adjacent sides of the great and second toes (Fig. 651), communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an interosseous branch to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The Musculo-cutaneous Nerve (n. peronaeus superficialis) (Fig. 650) supplies the muscles on the fibular side of the leg and the integument of the dorsum of the foot (Fig. 651). It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off muscular branches (rami musculares) to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg (Fig. 651).

The internal branch (n. cutaneus dorsalis medialis) of the musculo-cutaneous nerve passes in front of the ankle-joint, and divides into two dorsal digital branches (nn. digitales dorsales pedis), one of which supplies the inner side of the great toe, the other the adjacent sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joining with the anterior tibial nerve, between the great and second toes.

The external branch (n. cutaneus dorsalis intermedius), the smaller, passes along the outer side of the dorsum of the foot, and divides into two dorsal digital branches, the inner being distributed to the contiguous sides of the third and fourth toes, the outer to the opposed sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The branches of the musculo-cutaneous nerve supply all the toes excepting the outer side of the little toe, which is supplied by the external saphenous nerve. The adjoining sides of the great toe or second toe are also supplied by the internal branch of the anterior tibial. It frequently happens that some of the outer branches of the musculo-cutaneous are absent, their place being then taken by branches of the external saphenous nerve.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore, in psoas abscesses any or all of its branches may be irritated, causing severe pain in the parts to which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn
upward through the action of the Cremaster muscle, which is supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the ascending ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon, and its functions impaired, in some tumors growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stab in the groin. When this nerve is paralyzed, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there are complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural nerve, and by the ilio-inguinal nerve. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralyzed alone, but occasionally is paralyzed in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The great sciotic nerve is liable to be pressed upon by various pelvic tumors, giving rise to pain along its trunk, to which the term sciatica is applied. Tumors growing from the pelvic viscera, or bones, aneurism of some of the branches of the internal iliac artery, calcaneus in the bladder when of large size, accumulation of feces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumors growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciotic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large.

The sciotic nerve has been frequently cut down upon and stretched, or has been acupunctured for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxia, the anaesthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line is drawn from this point to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Gluteus maximus is slightly nearer the tuberosity of the ischium than to the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciotic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles respectively pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciotic nerve may also be stretched by what is known as the “dry” plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg. This last-named method is uncertain.

The position of the external popliteal nerve, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in subcutaneous division of the tendon. After it is divided,
a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided.

THE CEREBRAL OR CRANIAL NERVES (NERVI CEREBRALES).

The cranial nerves arise from some part of the cerebro-spinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura mater lining the base of the skull. Other names are also given to them, derived from the parts to which they are distributed or from their functions. Taken in their order, from before backward, they are as follows:

1st. Olfactory. 7th. Facial (Portio dura).
2d. Optic. 8th. Auditory (Portio mollis).
4th. Trochlear (Pathetic). 10th. Pneumogastric (or Vagus).

All the cranial nerves are connected to some part of the surface of the brain. This is termed their superficial or apparent origin. But their fibres may, in all cases, be traced deeply into the substance of the brain and to some special centre of gray matter, termed a nucleus. This is called their deep or real origin. The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

THE FIRST OR OLFAC TORY NERVE (N. OLFAC TORIUS) (Fig. 660).

The olfactory nerves are the special nerves of the sense of smell, and are about twenty in number on each side. These filaments constitute the first or olfactory nerves. They are given off from the under surface of the olfactory bulb, an oval mass of a grayish color, which rests on the cribiform plate of the ethmoid bone, and forms the anterior expanded extremity or a slender process of brain-substance, named the olfactory tract. The olfactory tract and bulb have already been described (p. 880). The olfactory tubercle (trigonum olfactorium) is a small triangular mass of gray matter between the diverging roots of the optic tract (p. 881).

Each nerve is surrounded by tubular prolongations from the dura mater and pia mater, the former being lost on the periosteum lining the nose, the latter in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; and an outer set, which is distributed over the superior turbinated bone, and the surface of the ethmoid in front of it. As the filaments descend, they unite in a plexiform network, and are believed by most observers to terminate by becoming continuous with the deep extremities of the olfactory cells.

The olfactory nerves differ in structure from other nerves in being composed exclusively of non-medullated fibres. They are deficient in the white substance of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres.
**The Olfactory Path** (Figs. 660 and 661).—Impressions from the upper portion of the Schneiderian mucous membrane pass along the olfactory nerves, reach the olfactory bulb, and traverse the olfactory tract to the cerebral hemisphere of the same side. The cortical area of the sense of smell is in the uncus hippocampi. Impressions which are conveyed by the internal root pass to Broca's area which is in front of the inner root of the olfactory tract, to the anterior extremity of the gyrus fornicatus, the cingulum, and the uncinate fasciculus to the cortical centre (Santee). Impressions travelling by the middle root reach the trigone and then pass to the cortical centre, as do those by way of the internal root, or they reach it by way of the anterior commissure (Santee). The outer root conducts impulses directly to the cortical area. Fig. 661 shows the olfactory path according to Dejerine.
Surgical Anatomy.—Destruction of the olfactory tract of one side causes loss of smell (anomia) on the side of the injury, because the olfactory tract is uncrossed. In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smell, and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the rapid substances being also odorous and simultaneously exciting the sense of smell. When the sense of smell is lost, an individual cannot distinguish the flavor of food, but he can distinguish that a substance is salt, or sweet, or bitter, or acid. The most usual cause of injury to the olfactory nerve is fracture of the base of the skull, the line of fracture passing through the cribiform plate of the ethmoid bone, but a blow upon the face, forehead, or back of the head, which does not produce fracture may injure the nerve.

THE SECOND OR OPTIC NERVE (N. OPTICUS) (Fig. 662).

The second or optic nerve, the special nerve of the sense of sight, is distributed exclusively to the eyeball. It joins the eyeball about one-eighth of an inch to the inner side of the axis of the globe, penetrates the fibrous coat and the vascular tunic, and at the optic disk is expanded and forms part of the retina. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the optic tracts.

The Optic Tract.—The optic tract, at its connection with the brain, is divided into two bands, external and internal. The external band is the larger; it arises from the external geniculate body and from the under part of the pulvinar of the optic thalamus, and is partly continuous with the brachium of the anterior or upper quadrigeminal body. The internal band curves around the crus ta, and passes beneath the internal geniculate body, with which it is connected, and then appears to lose itself in the brachium of the posterior or inferior quadrigeminal body. The fibres by which it is connected to the internal geniculate body are merely commissural, forming part of Gudden's commissure. From this origin the tract winds obliquely across the under surface of the crus cerebri, in the form of a flattened band, and is attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forward, is connected with the tuber cinereum and lamina cinerea. It finally joins with the tract of the opposite side to form the optic commissure.

The Optic Commissure (chiasma opticum) (Figs. 662 and 663, and p. 882) is somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellae, being bounded, above, by the lamina cinerea; behind by the tuber cinereum; on either side by the anterior perforated space. Within the commissure, the optic nerves of the two sides undergo a partial decussation (Figs. 663 and 664). The fibres which form the inner margin of each tract and posterior part of the commissure have no connection with the optic nerves. They simply pass across the commissure from one hemisphere of the brain to the other, and connect the internal geniculate bodies of the two sides. They are known as the inter-cerebral fibres of the optic commissure or the commissure of Gudden. The remainder and principal part of the optic com-
misure consists of two sets of fibres, crossed and uncrossed. The crossed fibres, which are the more numerous, occupy the central part of the chiasma, and pass from the optic tract of one side to the optic nerve of the other, decussating in the commissure with similar fibres of the opposite tract. The uncrossed fibres occupy the outer part of the chiasma, and pass from the tract of one side to the nerve of the same side.¹

The great majority of the fibres of the optic nerve consist of the afferent axones of nerve-cells in the retina. Some few, however, are efferent fibres, and grow out from the brain. The afferent fibres end in arborizations around the cells in the external geniculate body, pulvinar, nucleus of the motor oculi nerve, and the upper quadrigeminal body. The external geniculate body and pulvinar are sometimes termed the lower visual centres. From these nuclei other fibres are prolonged to the cortical half-visual centre, which, according to most observers, is situated in the cuneus, and probably also, to a small extent, in the curved portion of the occipital lobe (Fig. 664).

It should be stated that some fibres are detached from the optic tract, and pass through the crus cerebri to the nucleus of the third nerve. These fibres are small, and may be regarded as afferent branches for the sphincter pupillae and ciliary muscles. Other fibres pass to the cerebellum through its superior peduncles, while others, again, are lost in the pons.

The optic nerves arise from the forepart of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the pia mater and arachnoid. As each nerve passes through the corresponding optic foramen it receives a sheath from the dura mater; and as it enters the orbit this sheath subdivides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve and surrounds it as far as the sclerotic. The nerve passes forward and outward through the cavity of the orbit, pierces the sclerotic and choroid coats at the back part of the eyeball, about one-eighth of an inch to the nasal side of its centre, and expands into the retina. A small artery, the arteria centralis retinae, perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins.

The Optic Path (Fig. 664).—Impulses of sight originate in the retina. From the right half of each retina impulses pass by way of the optic nerves to the right optic tract. From the left half of each retina impulses pass by way of the optic nerves to the left optic tract. Impulses from the nasal half of each retina pass by decussated fibres to the opposite optic tract. Impulses from the temporal half of the retina pass by uncrossed fibres to the optic tract of the same side, although a few fibres may cross farther back through the quadrigeminal bodies. From the optic tract impulses pass to the external geniculate body, pulvinar, upper quadrigeminal body, and nucleus of the motor oculi nerve. From the external geniculate body and pulvinar impulses pass by way of the optic radius through the posterior segment of the internal capsule to the half-visual centre in the cuneus and the convexity of the occipital lobe. The superior quadrigeminal body and the nucleus of the third nerve produce ocular reflexes and the pupillary reflex.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of develop-

¹ A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. See also Henle, Nervenlehre, p. 306, ed 2.—Cf. of 15th English edition.
ment and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periostea as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinas.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.
THE THIRD OR MOTOR OCULI NERVE (N. OCULOMOTORIUS)
(Figs. 665, 666, 669).

The third or motor oculi nerve supplies all the muscles of the orbit except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris and the Ciliary muscle. It is rather a large nerve, of rounded form and firm texture.

Its apparent origin is from the inner surface of the crus cerebri, immediately in front of the pons Varolii. The deep origin may be traced through the substantia nigra and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct of Sylvius (Fig. 613). The nucleus of the third nerve also receives fibres from the sixth nerve of the opposite side. These will be referred to again in the description of the latter nerve. The nucleus of the third nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle. The nerves to the different muscles appear to take their origin from before backward, as follows: Inferior oblique, Inferior rectus, Superior rectus and Levator palpabrae, Internal rectus; while from the anterior end of the nucleus the fibres for accommodation and for the Sphincter pupillae take their origin.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, and then pierces the dura mater in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus (Figs. 454 and 455); above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the fifth. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle (Fig. 665). On passing through the fissure, the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve (Fig. 675).

The Superior Division (ramus superior) (Fig. 666).—The superior division, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpabrae.
The Inferior Division (ramus inferior) (Fig. 666).—The inferior division, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch, radix brevis ganglii ciliaris, is given off to the lower part of the lenticular ganglion and forms its short or motor root (Figs. 666, 669, and 670). It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Surgical Anatomy.—Paralysis of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones entering into the formation of the sphenoidal fissure; fracture of the orbit. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebrae being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the sphincter pupillae, the ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the Ciliary muscle, or constriction of the pupil (myosis), from irritation of the sphincter of the pupil.

THE FOURTH OR TROCHLEAR NERVE (N. TROCHLEARIS) (Figs. 665 and 669).

The fourth or trochlear nerve or Patheticus, the smallest of the cranial nerves, supplies the Superior oblique muscle.

The apparent origin, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons Varolii, but the fibres can be traced backward behind the corpora quadrigemina to the valve of Vieussens, on the upper surface of which the two nerves decussate, decussatio nervorum trochlearum. Its deep origin may be traced to a nucleus in the floor of the aqueduct of Sylvius immediately below that of the third nerve, with which it is continuous (Fig. 613).

Emerging from the upper end of the valve of Vieussens, the nerve is directed outward across the superior peduncle of the cerebellum, and then winds forward
around the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth (Figs. 454 and 455). It crosses the third nerve and enters the orbit through the sphenoidal fissure (Fig. 675). It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward, above the origin of the Levator palpebrae, and finally enters the orbital surface of the Superior oblique muscle. In the outer wall of the cavernous sinus this nerve is not infrequently blended with the ophthalmic division of the fifth.

**Branches of Communication.**—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve.

**Branches of Distribution.**—It gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

**Surgical Anatomy.**—The fourth nerve when *paralyzed* causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing *diplopia* or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

**THE FIFTH, TRIGEMINAL OR TRIFACIAL NERVE (N. TRIGEMINUS)**

(Figs. 665, 667 668, 669, 670, 671, 672, 673, 674).

The fifth, trigeminal or trifacial nerve is the largest cranial nerve. It resembles a spinal nerve (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions, *portio major*, are entirely sensory, the third division, *portio minor*, is partly sensory and partly motor. It arises by two roots: of these the anterior is the smaller, and is the *motor root* (Fig. 613); the posterior, the larger and *sensory root*. Its *superficial origin* is from the side of the pons Varolii, nearer to the upper than the lower border (Fig. 613). The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The *deep origin* of the larger or sensory root is chiefly from a long tract in the medulla, the *lower sensory nucleus*, which is continuous below with the substantia gelatinosa of Rolando (Fig. 607). The fibres from this nucleus form the so-called *ascending root of the fifth nerve* (Fig. 607); they pass upward through the pons and join with fibres from the locus caeruleus or *upper sensory nucleus* (Fig. 613), which is situated to the outer side of the nucleus, from which the lower part of the motor root takes origin. The *deep origin* of the smaller or motor root is derived partly from a nucleus embedded in the gray matter of the upper part of the floor of the fourth ventricle and partly from a collection of nerve-cells situated at the side of the aqueduct of Sylvius, from which the fibres pass downward under the name of the *descending root of the fifth nerve* (Fig. 613).

The two roots of the nerve pass forward below the tentorium cerebelli as it bridges over the notch on the inner part of the superior border of the petrous portion of the temporal bone (Fig. 668); they then run between the bone and the dura
mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form the large semilunar or Gasserian ganglion (Figs. 667 and 668), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it (Figs. 667 and 668).

The Gasserian or Semilunar Ganglion\(^1\) (ganglion semilunare) (Figs. 667, 668, 669, 670, 671, 672, and 673).—The Gasserian or semilunar ganglion is lodged in an osteo-fibrous space, the cavum Meckelii (Figs. 545 and 668), near the apex of the petrous portion of the temporal bone. The ganglion is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the large, superficial petrosal nerve lies underneath the ganglion.

**Branches of Communication.**—This ganglion receives on its inner side filaments from the carotid plexus of the sympathetic.

**Branches of Distribution.**—It gives off minute branches to the tentorium cerebelli and the dura mater in the middle fossa of the cranium. From its anterior border, which is directed forward and outward, three large branches proceed—the opthalmic, superior maxillary, and inferior maxillary. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior

---

\(^1\) A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasseri." Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was professor at Padua, 1545-1605. (See Hyrtl, Lehrbuch der Anatomic, p. 895 and p. 55.)—Ed. of 15th English edition.
maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

**Ophthalmic Nerve** (*n. ophthalmicus*) (Figs. 665, 667, 668, 669, 670, 671, 672, and 673).—The ophthalmic, or **first division** of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossae, and the integument of the eyebrow, forehead, and nose (Fig. 674). It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about an inch in length, which passes forward along the outer wall of the cavernous sinus (Figs. 454 and 455), below the other nerves (Fig. 667), and just before entering the orbit, through the sphenoidal fissure, divides into three branches—**lachrymal**, **frontal**, and **nasal** (Figs. 665, 669, 670, 671).

**Branches of Communication.**—The ophthalmic nerve gives off in the cavernous sinus a branch to the dura mater (*n. tentorii*), is joined by filaments from the cavernous plexus of the sympathetic, and gives off minute branches to communicate with the third and sixth nerves, and not infrequently with the fourth.

**Branches of Distribution.**—It gives off recurrent filaments which pass between the layers of the tentorium, and then divide into—

- **Lachrymal.**
- **Frontal.**
- **Nasal.**

**The Lachrymal Nerve** (*n. lacrimalis*) (Figs. 665, 669, 670, and 671).—The lachrymal is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the fourth nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the fourth. It passes forward in a separate tube of dura mater, and enters the orbit through the narrowest part of the sphenoidal fissure (Fig. 675). In the orbit it runs along the upper border of the External rectus muscle, with the lachrymal artery, and communicates with the temporo-malar branch of the superior maxillary nerve. It enters the lachrymal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lachrymal nerve is occasionally absent, when its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lachrymal is substituted for it.
Fig. 670.—Plan of the fifth cranial nerve. (The lenticular ganglion is displaced from its normal position. The portion where the short root enters is really the inferior angle; in the diagram it is the superior angle.) (After Flower.)
The Frontal Nerve (n. frontalis) (Figs. 665, 669, and 670).—The frontal is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the sphenoidal fissure (Fig. 675), and runs forward along the middle line, between the Levator palpebrae and the periosteum. Midway between the apex and the base of the orbit it divides into two branches, supratrochlear and supra-orbital.

The Supratrochlear Branch (n. supratrochlearis) (Figs. 665 and 670), the smaller of the two, passes inward, above the pulley of the superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii andOccipito-frontalis muscles, and, dividing into branches which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper lid.

The Supraorbital Branch (n. supraorbitalis) (Figs. 675 and 670) passes forward through the supraorbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead and terminates in cutaneous and pericranial branches.

The cutaneous branches, two in number, an inner and an outer, supply the integument of the cranium as far back as the vertex. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis.

The pericranial branches are distributed to the pericranium over the frontal and parietal bones.

The Nasal Nerve (n. nasociliaris) (Figs. 665, 669, and 670).—The nasal nerve is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit by way of the sphenoidal fissure (Fig. 675) between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Superior rectus and Superior oblique muscles, to the inner wall of the orbit, where it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the front of the cribiform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose (Fig. 672), where it divides into two branches, an internal and an external branch. The internal branch (rami nasales mediales) supplies the mucous membrane near the forepart of the septum of the nose. The external branch (rami nasales laterales) descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the forepart of the outer wall of the nares as far as the inferior spongy bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

Branches.—The branches of the nasal nerve are the ganglionic, ciliary, and infra trochlear.

The Ganglionic Branch, or the long root of the ciliary ganglion (radix longa ganglii ciliaris) (Figs. 666, 669, and 670), is a slender branch, about half an inch in length, which usually arises from the nasal nerve, between the two heads of the External rectus muscle. It passes forward on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The Long Ciliary Nerves (nn. ciliares longi) (Fig. 670), two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short
ciliary nerves (Figs. 666, 669, and 670) from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forward between it and the choroid, are distributed to the ciliary muscle, iris, and cornea.

The Infra trochlear Branch (n. infratrochlearis) (Figs. 665 and 670) is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus muscle, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, the lachrymal sac, and the caruncula lacrimalis.

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the ophthalmic ganglion; with the second division, the spheno-palatine or Meckel's ganglion; and with the third, the otic and submaxillary ganglia. All the four receive sensory filaments from the fifth nerve, and motor and sympathetic filaments from various sources; these filaments are called the roots of the ganglia.

The Ophthalmic, Lenticular or Ciliary Ganglion (ganglion ciliare) (Figs. 666, 669, and 670) is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its exposure by dissection somewhat difficult.

Its branches of communication or roots are three, all of which enter its posterior border. One, the long or sensory root (radix longa ganglii ciliaris), is derived from the nasal branch of the ophthalmic and joins the superior angle of the ganglion. The second, the short or motor root (radix brevis ganglii ciliaris), is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root (radix sympathetic ganglii ciliaris), is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the spheno-palatine ganglion.

Its branches of distribution are the short ciliary nerves (nn. ciliares breves) (Figs. 666, 669, and 670). These are delicate filaments, from six to ten in number, which arise from the forepart of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves from the nasal nerve. They pierce the sclerotic at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinae.

The circular fibres of the iris are innervated by the third nerve; the radiating fibres are innervated by the sympathetic.

The Superior Maxillary Nerve (n. maxillaris) (Figs. 667, 668, 669, 670, 671, and 672).—The superior maxillary or second division of the fifth is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band (Fig. 667), and, passing horizontally forward, it leaves the skull through the foramen rotundum (Fig. 668), where it becomes more cylindrical in form and firmer in texture. It then crosses the sphenomaxillary fossa (Fig. 67), enters the orbit through the sphenomaxillary fissure, traverses the infraorbital canal in the floor of the orbit, and appears upon the face of the infraorbital fora-
men. After it enters the infraorbital canal the nerve is usually called the infratrochlear (n. infraorbitalis), and the infraorbital nerve is the terminal branch of the superior maxillary nerve (Fig. 671). At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the sphenomaxillary fossa. 3. Those in the infraorbital canal. 4. Those on the face.

In the cranium . . . Meningeal.
   Spheno-maxillary fossa . . {Orbital or temporo-malar.
   {Spheno-palatine.
   {Posterior superior dental.
   {Middle superior dental.
   {Anterior superior dental.
   Palpebral.
On the face . . . . {Nasal.
   {Labial.

The Meningeal Branch (n. meningeus medius).—The meningeal branch is given off by the superior maxillary nerve directly after its origin from the Gasserian ganglion; it accompanies the middle meningeal artery and supplies the dura mater of the middle fossa of the base of the skull.

The Orbital or Temporo-malar Branch (n. zygomaticus) (Figs. 669, 670, and 671).—The orbital or temporo-malar branch arises in the sphenomaxillary fossa, enters the orbit by the sphenomaxillary fissure, and divides at the back of that cavity into two branches, temporo and malar.

The Temporal Branch (ramus zygomaticotemporalis) runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal; and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and the substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and the auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The Malar Branch (ramus zygomaticofacialis) passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek, where it is named the subcutaneous malaë. It joins with the facial and the palpebral branches of the superior maxillary.

The Spheno-palatine Branches (nn. sphenopalatini) (Figs. 670 and 671).—The sphenopalatine branches, two in number, descend to the sphenopalatine ganglion, of which ganglion they are the sensory or short roots.

The Posterior Superior Dental Branches (rami alveolares superiores posteriores) (Figs. 670 and 671).—The posterior superior dental branches arise from the trunk of the nerve just as it is about to enter the infraorbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek, superior gingival branches (rami gingivales superiores). They then enter the posterior dental canals on the zygomatic surface of the superior maxillary bone, and, passing from behind forward in the substance of the bone,
communicate with the middle dental nerve by a plexus formation, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The Middle Superior Dental Branch (*ramus alveolaris superior medius*) (Fig. 670).—The middle superior dental branch is given off from the superior maxillary nerve in the back part of the infraorbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches by a plexus formation. At its point of communication with the posterior branch, above the root of the second bicuspid tooth, is a slight thickening which has received the name of the *ganglion of Valentin*; and at its point of communication with the anterior branch is a second enlargement, which is called the *ganglion of Bochdalek*. Neither of these is probably a true ganglion.

The Anterior Superior Dental Branch (*ramus alveolaris superior anteriores*) (Fig. 670).—The anterior superior dental branch, of large size, is given off from the superior maxillary nerve just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve by a plexus, and gives off a *nasal branch*, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the forepart of the inferior meatus and the floor of the cavity, communicating with the nasal branches from Meckel’s ganglion.

The *superior dental plexus* (*plexus dentalis superior*) is formed by twigs of the three superior dental nerves. From the plexus come the nerves which supply the
teeth of the upper jaw (rami dentales superiores) and the gums (rami gingivales superiores).

The branches upon the face are known as the rami n. infraorbitalis (Fig. 671). There are three sets of them.

The Palpebral Branches (rami palpebrales inferiores).—The palpebral branches pass upward beneath the Orbicularis palpebrarum muscle. They supply the integument and conjunctiva of the lower eyelid, with sensation, joining at the outer angle of the orbit with the facial nerve and the malar branch of the orbital.

The Nasal Branches (rami nasales interni).—The nasal branches pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The Labial Branches (rami labiales superiores).—The labial branches, the largest and most numerous, descend beneath the Levator labii superioris muscle, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and the labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the infraorbital plexus.

The Spheno-palatine or Meckel’s Ganglion (ganglion sphenopalatinum) (Figs. 670 and 672).—The sphenopalatine ganglion, the largest of the cranial ganglia, is deeply placed in the sphen-maxillary fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

Branches of Communication.—Like the other ganglia of the fifth nerve, it possesses a motor, a sensory, and a sympathetic root. Its sensory root is derived from the superior maxillary nerve through its two sphenopalatine branches (p. 1032). These branches of the nerve are given off in the sphen-maxillary fossa and descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its motor root is derived from the facial nerve through the large superficial petrosal nerve, and its sympathetic root from the carotid plexus, through the large deep petrosal nerve. These two nerves join together before their entrance into the ganglion to form a single nerve, the Vidian.

The Large or Great Superficial Petrosal Branch (n. petrosus superficialis major) (Fig. 676) is given off from the geniculate ganglion of the facial nerve in the aquaeductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward, being contained in a groove on the anterior surface of the petrous portion of the temporal bone and lying beneath the dura mater. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the Vidian nerve.

The Large or Great Deep Petrosal Branch (n. petrosus profundus) (Fig. 677) is given off from the carotid plexus of the sympathetic upon the internal carotid artery, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and joins with the large superficial petrosal nerve to form the Vidian.

The Vidian Nerve (n. canalis pterygoidei) (Figs. 670 and 672), formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes forward, through the Vidian canal, with the artery of the same name, and is joined by a small ascending nervous branch, the sphenoidal branch, from the otic ganglion. Finally, it enters the sphen-maxillary fossa, and joins the posterior angle of Meckel’s ganglion.
Branches of Distribution of the Spheno-palatine Ganglion.—Its branches of distribution are divisible into four groups: ascending, which pass to the orbit; descending, to the palate; internal, to the nose; and posterior branches, to the pharynx and nasal fossae.

The Ascending Branches (rami orbitales) are two or three delicate filaments, which enter the orbit by the sphenoo-maxillary fissure, and supply the periosteum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bones to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The Descending or Palatine Branches (nn. palatini) (Figs. 670 and 672) are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the sphenoo-palatine branches of the superior maxillary nerve, and are three in number—anterior, middle, and posterior.

The anterior or large palatine nerve (n. palatinus anterior) descends through the large posterior palatine canal, emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the naso-palatine nerve (p. 1036). While in the posterior palatine canal it gives off inferior nasal branches (rami nasales posteriores inferiores), which enter the nose through openings in the palate bone, and ramify over the inferior turbinate bone, the middle and the inferior meatus; and at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The middle or external palatine nerve (n. palatinus medius) descends through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The posterior or small palatine nerve (n. palatinus posterior) descends with a minute artery through the small posterior palatine canal, emerging by a separate
opening behind the posterior palatine foramen. It supplies the Levator palati
and Azygos uvulae muscles,\(^1\) the soft palate, tonsil, and uvula. The middle and
posterior palatine join with the tonsillar branches of the glossopharyngeal to form
the plexus around the tonsil, the *circulus tonsillaris."

The **Internal Branches** are distributed to the septum and outer wall of the nasal
fossae. They are the **posterior superior nasal** and the **naso-palatine.**

The **posterior superior nasal branches** (*rami nasales posteriores superiores*), three
in number, enter the back part of the nasal fossa by the sphenopalatine foramen.
They supply the mucous membrane covering the superior and middle spongy bones,
and that lining the posterior ethmoidal cells, a few being prolonged to the upper
and back part of the septum.

The **naso-palatine nerve** (*n. nasopalatinus*) has been called the **nerve of Scarpa**
and also the **nerve of Coturnius.** It enters the nasal fossa through the sphenopala-
tine foramen, and passes inward across the roof of the nose, below the orifice
of the sphenoid sinus, to reach the septum; it then runs obliquely downward and
forward along the lower part of the septum, to the anterior palatine foramen,
lying between the periosteum and mucous membrane. It descends to the roof of
the mouth through the **anterior palatine canal** (Fig. 672). The two nerves are here
contained in separate and distinct canals, situated in the intermaxillary suture, and
termied the **foramina of Scarpa,** the left nerve being usually anterior to the right
one. In the mouth they become united, supply the mucous membrane behind
the incisor teeth, and join with the anterior palatine nerve. The naso-palatine
nerve furnishes a few small filaments to the mucous membrane of the septum.

The **Posterior Branches** are the **pharyngeal or pterygo-palatine** and the upper
posterior nasal branches.

The **pharyngeal or pterygo-palatine nerve** (Figs. 670 and 672) is a small branch
arising from the back part of the sphenopalatine ganglion, being generally blended
with the Vidian nerve. It passes through the **pterygo-palatine canal** with the
pterygo-palatine artery, and is distributed to the mucous membrane of the upper
part of the pharynx, behind the Eustachian tube.

The **upper posterior nasal branches** are a few twigs given off from the posterior
part of the sphenopalatine ganglion, which run backward in the sheath of the
Vidian nerve to the mucous membrane at the back part of the roof, septum, and
superior meatus of the nose and that covering the end of the Eustachian tube.

The **Mandibular or Inferior Maxillary Nerve** (*n. mandibularis*) (Figs. 667,
669, 670, and 671).—The **inferior maxillary** or third division of the **fifth nerve**
distributes branches to the teeth and gums of the lower jaw, the integument of the
temple and external ear, the lower part of the face and lower lip, and the muscles
of mastication; it also supplies the tongue with a large branch. It is the largest of
the three divisions of the fifth, and is made up of two roots: a **large or sensory root,**
proceeding from the inferior angle of the Gasserian ganglion; and a **small or motor
root,** which passes beneath the ganglion and unites with the sensory root just after
its exit from the skull through the **foramen ovale** (Figs. 667, 668, 670, and 671).
Immediately beneath the base of the skull this nerve divides into two trunks,
**anterior** and **posterior.** Previous to its division the primary trunk gives off from
its inner side a recurrent branch and the nerve to the Internal pterygoid muscle.

The **Recurrent or Meningeal Branch** (*n. spinosus*).—The recurrent or meningeal
branch is given off directly after the exit of the mandibular nerve from the foramen
ovale. It passes backward into the skull through the foramen spinosum with the
middle meningeal artery. It divides into two branches, **anterior** and **posterior,** which
accompany the main divisions of the artery and supply the dura mater. The pos-

\(^1\) It is probable that this is not the true motor supply to these muscles, but that they are supplied by the
spinal accessory through the pharyngeal plexus.—Ed. of 15th English edition.
terior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The Internal Pterygoid Nerve (n. pterygoideus internus) (Fig. 670).—The internal pterygoid nerve, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The anterior and smaller division of the inferior maxillary nerve, which receives nearly the whole of the motor root of the fifth nerve, divides into branches which supply the muscles of mastication. They are the massteric, deep temporal, buccal, and external pterygoid branches (Figs. 670 and 671).

The Masseteric Branch (n. massetericus) passes outward, above the External pterygoid muscle, in front of the temporo-mandibular articulation and behind the tendon of the temporal muscle; it crosses the sphenoid notch with the masseteric artery, to the deep surface of the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle, and a filament to the articulation of the jaw.

The Deep Temporal Branches (nn. temporales profundi), two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The posterior branch (n. temporalis profundus posterior), of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The anterior branch (n. temporalis profundus anterior) is frequently given off from the buccal nerve; it is reflected upward, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Sometimes there are three deep temporal branches, and if this maintains the third branch, the middle deep temporal, passes outward above the External pterygoid muscle, and runs upward on the bone to enter the deep surface of the Temporal muscle.

The Buccal or Buccinator Branch (n. buccinatorius) passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid processes of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator muscle, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The superior or upper branch supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve around the facial vein. The inferior or lower branch passes forward to the angle of the mouth; it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.1

The External Pterygoid Nerve (n. pterygoideus externus) is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the mandibular nerve. It enters the muscle on its inner surface.

The posterior and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual (gustatory), and inferior dental (Figs. 670, 671).

The Auriculo-temporal Nerve (n. auriculotemporalis) (Fig. 673) generally arises by two roots, between which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external car and the condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two temporal branches.

1. There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.—Ed. of 15th English edition.
The branches of communication are with the facial and with the otic ganglion. The branches of communication with the facial (rami anastomotici cum n. facialis), usually two in number, pass forward from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The branches of distribution are—

<tr>
<td>Branches to the meatus auditorius.</td>
<td>Parotid.</td>
</tr>
<tr>
<td>Superficial temporal.</td>
<td></td>
</tr>
</tbody>
</table>

The anterior auricular branches (nn. auriculares anteriores) are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

Branch to the external auditory meatus (n. meatus auditorii externi) divides into two. The two nerves enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani (ramus membranae tympani).

A branch to the temporo-mandibular articulation, the articular branch, is usually derived from the auriculo-temporal nerve.

The parotid branches (rami parotidei) supply the parotid gland.

The superficial temporal branches (rami temporales superficiales) accompany the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve, and with the temporal branch of the temporo-malar, from the superior maxillary.

The Lingual Nerve or Gustatory Nerve (n. lingualis) (Figs. 670 and 671).—The lingual or gustatory nerve supplies the papillae and mucous membrane of the anterior two-thirds of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of this nerve, and is occasionally joined to it by a branch which may cross the internal maxillary artery. The chorda tympani nerve also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Superior constrictor of the pharynx and the Stylo-glossus muscles, and then between the Hyo-glossus muscle and the deep part of the submaxillary gland; the nerve finally runs across Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The branches of communication are with the facial through the chorda tympani, with the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The chorda tympani branch of the facial joins the lingual nerve under the external pterygoid muscle and is distributed with the lingual to the tongue. The hypoglossal nerve and the lingual nerve lie near together, over the Hyo-glossus muscle, and the two nerves are joined by loops (rami anastomotici cum n. hypoglosso). The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The branches of distribution supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillae and mucous membrane of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve. The lingual fibres are fibres of common sensation. The chorda tympani fibres which join the lingual nerve are probably taste-fibres.
The Inferior Dental Nerve (n. alveolaris inferior) (Figs. 670 and 671).—The inferior dental is the largest of the branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forward in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The Branches of the inferior dental are: the mylo-hyoid, dental, incisor, and mental.

The Mylo-hyoid (n. mylohyoideus) is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric.

The Dental Branches supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth; each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The Incisor Branch is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The dental branches and the incisor branch form a plexus (plexus dentalis inferior), and from this plexus come the branches to the teeth (rami dentales inferiores) and to the gums (rami gingivales inferiores).

The Mental Branch (n. mentalis) emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris muscle into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the otic with the trunk of the nerve, and the submaxillary with its lingual branch.

Otic or Arnold's Ganglion (ganglion oticum) (Figs. 670 and 673).—The otic or Arnold's ganglion is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, externally, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; internally, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; behind, it lies in the middle meningeal artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short delicate filaments. From this nerve the ganglion may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid perhaps contain sensory fibres. The otic ganglion communicates with the glossopharyngeal and facial nerves through the small superficial petrosal nerve (Figs. 673 and 676) continued from the tympanic plexus, and through this communication it probably receives its sensory root from the glossopharyngeal and its motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve (ramus anastomoticus cum n. auriculotemporali). This communicating filament is probably a branch from the glossopharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland. A slender filament, the sphenoidal, ascends from it to the Vidian nerve.

Branches of Distribution.—Its branches of distribution are a filament to the Tensor tympani (n. tensoris tympani) and one to the Tensor palati (n. tensoris veli
THE NEUROUS SYSTEM

palatini). The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani (ramus anastomoticus cum n. chorda tympani).

The Submaxillary Ganglion (ganglion submaxillare) (Figs. 670 and 671).—The submaxillary ganglion is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual or gustatory nerve.

Branches of Communication.—This ganglion is connected with the lingual nerve by a few filaments (rami communicantes cum n. lingualis), which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Fig. 673.—The otic ganglion and its branches.

Branches of Distribution.—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton’s duct, some being lost in the submaxillary gland (rami submaxillares). The branch of communication from the lingual nerve to the forepart of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the lingual nerve, and by it are conveyed to the sublingual gland and the tongue.

Summary of the Distribution and Connections of the Fifth Nerve.—It is the chief sensory nerve of the face, the anterior half of the scalp, the mouth, nasal cavity, lips, teeth, anterior two-thirds of the tongue, orbit, and eyeball. The clearly defined cutaneous distributions of the branches are shown in Fig. 674. The motor portion of the nerve supplies the muscles of mastication, the mylo-hyoid, and the anterior belly of the digastric. By way of branches from the otic ganglion it supplies the Tensor tympani and Tensor palati muscles, and by way of branches from the spheno-palatine ganglion perhaps supplies the Levator palati and Azygos uvulae muscles, although it is more probable that these muscles
receive their motor influence by the spinal accessory through the pharyngeal plexus. The ganglia associated with the nerve create communications with the sympathetic, the motor oculi, the facial, and the glossopharyngeal, and through these ganglia, as Prof. Cunningham says, "important organs, areas, and muscles" are innervated. The trigeminal communicates many times with the facial, and thus gives sensory fibres to the "muscles of expression supplied by the facial nerve."\(^1\)

**Surface Marking.**—It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and pass on to the face: the terminal branch of the first division emerging through the supraorbital foramen; that of the second through the infraorbital foramen; and the third through the mental foramen. The supraorbital foramen is situated at the junction of the internal and middle third of the supraorbital arch. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspids of the lower jaw, it will pass over the infraorbital and mental foramina, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

**Surgical Anatomy.**—In *fracture of the base of the skull*, the fifth nerve or one of its branches may be injured. It seems certain that occasionally, though seldom, the fifth nerve may be actually divided by such an injury. The fifth nerve may be affected in its entirety, or its sensory or motor root may be affected, or one of its primary main divisions. In injury to the sensory root there is anesthesia of the half of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed, if the eye is not temporarily protected with a watch-glass, by destructive inflammation of the cornea, partly, it is held, from loss of trophic influence, and partly, it is certain, from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of *neuralgia*, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The *supraorbital nerve* may be exposed

\(^1\) Cunningham's Text-book of Anatomy.
by making an incision an inch and a half in length along the supraorbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis palpbralium having been divided, the nerve can be found easily emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it should be removed. The infraorbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by better results than has nerve resection. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb of the incision passing along the lower margin of the orbit, the other from the centre of the first cut vertically down the cheek toward the angle of the mouth. The nerve is then found, is divided, and a piece of silk is tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including the infraorbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the sphenico-maxillary fossa exposed. The infraorbital canal is now opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.\(^1\) The mental branch of the inferior dental nerve may be divided at its exit from the foramen through an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the trunk of the inferior dental nerve may be resected through an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine is then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve is dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it is by traction on the end exposed in the trephine-hole, drawn out entire, and cut off as high up as possible.\(^2\) The inferior dental nerve has also been divided through an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Buc- cinator muscle just in front of the anterior border of the ramus of the lower jaw (Stimson). In inveterate neuralgia of one or two of the branches of the fifth nerve a peripheral operation may cure the case, but seldom does. It often gives relief, perhaps for months. In neuralgia of the second division or third division, or of the second division and third division, Abbe, of New York, opens the skull and divides the nerve or nerves by an intracranial operation, removes a piece of nerve so as the foramen of exit is empty, and covers the foramen with rubber tissue, to hinder regrowth of the nerve. Other operators, after removing a piece from each nerve, have plugged the foramina of the exit with dentists' cement or silver-foil.

**,Rose's method** of neuroectomy is very valuable for neuralgia of the second division. It is a modification of the Braun-Lossen method. The infraorbital nerve is exposed, a ligature is tied about it, the roof of the infraorbital canal is chiselled open, and the nerve is freed as far back as possible. An incision is made from below the external angular process outward along the zygoma to in front of the lobe of the ear, downward to just above the angle of the jaw, and forward for two inches. The flap is raised and the zygoma is exposed. The root of the zygoma is drilled at two points, and the zygomatic process of the temporal bone is drilled at two points. The bone is sawed in two places between the drill-holes. The freed arch is lifted down and back, the tendon of the temporal muscle is drawn backward, and the pterygo-maxillary fossa is thus exposed. The internal maxillary artery is divided between two ligatures. The External pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. The superior maxillary nerve is grasped and twisted off as near the ganglion as possible. The entire nerve is then drawn back from the infraorbital foramen and removed. The wound is then closed. If the third division is also haunted by neuralgia, it too should be removed a few weeks after the performance of Rose's operation.

If a peripheral operation fails, or if all the branches of the fifth are involved, the Gasserian ganglion must be removed or the sensory root of the fifth must be divided, as suggested by Frazier and Spiller.

**Removal of the Gasserian ganglion** was suggested by J. Ewing Mears in 1884, and was first carried out by Rose in 1890.

The method chiefly in vogue was devised by Hartley, and was first performed by him in 1891. An osteoplastic flap is made in front of the ear, the dura is exposed and lifted. Following Krause's advice, the third division is exposed and clamped. The second division is exposed and clamped. The nerves are loosened from their beds and then are rolled about the clamps. This twisting

---

1 Carnochan, American Journal of the Medical Sciences, 1838, p. 136.
pulls out the ganglion intact along with the motor root, and also the sensory root from the
pons.
A difficulty in the Hartley operation is the danger of division of the meningeal artery. If
this happens, the surgeon may be able to arrest bleeding and proceed with the operation. If
the vessel is torn off at the foramen spinosum, it will be necessary to pack the wound and post-
pone any further operative manipulation for forty-eight hours.

Dr. Harvey Cushing has modified Hartley's operation by trephining the wall of the temporal
fossa very low down. He opens the skull below the arch of the meningeal vessels, and thus avoids
the meningeal at the foramen spinosum, and also the sulus arteriosus of the parietal bone.

After the removal of the ganglion, Professor Keen, in order to prevent undue inflammation of
the eye, sews the eyelids of the affected side together, leaving a space open at each angle, and
covers the eye with a watch-crystal. Boracic acid solution is flushed into the opening at the external
angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in
cancerous disease of the tongue. This may be done in that part of its course where it lies below
and behind the last molar tooth. If a line is drawn from the middle of the crown of the last
molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind
the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If
the knife is entered three-quarters of an inch behind and below the last molar tooth and carried
down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth.
where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over
to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous
membrane by the side of the tongue and can be easily seized with a sharp hook and divided or
a portion excised. This is a simple enough operation on the cadaver, but when the disease is
extensive and has extended to the floor of the mouth, as is generally the case when division of
the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 669).

The sixth or abducens nerve supplies the External rectus muscle. Its superficial origin is by several filaments from the constricted part of the pyramid, close
to the pons, or from the lower border of the pons itself, in the groove between this
body and the medulla. Its deep origin is from the upper part of the floor of the
fourth ventricle, close to the median line, beneath the eminentia teres (Fig. 613.)

From the nucleus of the sixth nerve fibres pass through the posterior longitudinal
bundle to the oculo-motor nucleus of the opposite side and into the third nerve,
along which they are carried to the Internal rectus muscle. The External rectus
of one eye and the Internal rectus of the other may therefore be said to receive
their nerves from the same nucleus—a factor of great importance in connection
with the conjugate movements of the eyeball, and one that may explain certain
paralytic phenomena of the Recti muscles, which are often associated with lesions
in the pons.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone,
runs through a notch immediately below the posterior clinoid process, and enters
the cavernous sinus. It passes forward through the sinus, lying on the outer side of
the internal carotid artery (Fig. 454). It enters the orbit through the sphenoidal
fissure, and lies above the ophthalmic vein, from which it is separated by a lamina
of dura mater (Fig. 675). It then passes between the two heads of the External
rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.—It is joined by several filaments from the
carotid and cavernous plexuses, and by one from the ophthalmic nerve.

Relations to Each Other of the Third, Fourth, Ophthalmic Division of the Fifth and
Sixth Nerves as They Pass to the Orbit.—The third, the fourth, the ophthalmic
division of the fifth, and the sixth nerves, as they pass to the orbit, bear a certain
relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the
cavity of the orbit, which will now be described.

In the Cavernous Sinus (Figs. 454 and 455) the third, fourth, and ophthalmic
division of the fifth are placed on the outer wall of the sinus, in their numerical
order, both from above downward and from within outward. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth nerve approaches the rest, so that their relative position becomes considerably changed.

In the Sphenoidal Fissure (Fig. 675) the fourth nerve and the frontal and lachrymal branches of the ophthalmic division of the fifth lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the third nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the third nerve; and the sixth nerve lowest of all.

In the Orbit (Figs. 665 and 669) the fourth nerve and the frontal and lachrymal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the fourth nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebrae muscle, and the lachrymal nerve on the External rectus muscle. Next in order comes the superior division of the third nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the third nerve and the sixth nerve, which lies on the outer side of the orbit.

Surgical Anatomy.—It is often stated that the sixth nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually ruptured. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arterio-venous aneurism. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 676, 677, 678).

The seventh or facial nerve or Portio Dura is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the External ear; the posterior belly of the Digastric, and the Stylo-hyoid. Its chorda tympani branch is the nerve of taste for the anterior two-thirds of the tongue and the vaso-dilator nerve of the submaxillary and sublingual glands; its tympanic branch supplies the Stapedius.

Its superficial origin is from the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. Its deep origin is from a nucleus situated in the floor of the fourth ventricle, beneath the superior fovea (Fig. 613).
The facial nucleus is deeply placed in the reticular formation of the lower part of the pons, a little external and ventral to the nucleus of the sixth nerve. From this origin the fibres pursue a curved course in the substance of the pons. They first pass backward and inward, and then turn upward and forward, forming the fasciculus teres, which produces an eminence, the eminentia teres, on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the sixth nerve, to reach their superficial origin between the olivary and restiform bodies. From the nucleus of the third nerve some fibres arise which descend in the posterior longitudinal bundle and join the facial just before it leaves the pons; these fibres are said to supply the anterior belly of the Occipito-frontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

The auditory nerve (portio mollis) lies to the outer side of the facial nerve; and between the two is a small fasciculus, the pars intermedia of Wrisberg (n. intermedius), which arises from the medulla and joins the facial nerve in the internal auditory meatus. The deep origin of the pars intermedia is from the upper end of the nucleus of the glosso-pharyngeal nerve, and at its emergence it is frequently connected with both nerves.

The pars intermedia may be regarded as the sensory root of the facial nerve, analogous to the sensory root of the fifth, and its real nucleus of origin would then consist of the geniculate ganglion.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the internal auditory meatus with the auditory nerve. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve and the pars intermedia is placed between the two, and joins the inner angle of the geniculate ganglion. Occasionally a few of its fibres pass into the auditory nerve. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani.

At the bottom of the meatus the facial nerve enters the aquaeductus Fallopii, and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the stylo-mastoid foramen (Figs. 49 and 676). It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it then bends suddenly backward and arches downward behind the tympanum to the stylo-mastoid foramen. At the point in the aqueduct of Fallopis where the nerve changes its direction (geniculum n. facialis), it presents a reddish gangliform swelling, the geniculate ganglion (ganglion genicolii), which is also called the intumescentia ganglioformis (Fig. 676). The geniculate ganglion receives a branch from the vestibular division of the auditory nerve, which probably carries fibres of the pars intermedia. On emerging from the stylo-mastoid foramen the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, temporo-facial and cervico-facial, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of pes anserinus is given to the divisions of the facial nerve in and near the parotid gland.
**Branches of Communication** (Fig. 677).—The communications of the facial nerve may be thus arranged:

In the internal auditory meatus . . . . . . With the auditory nerve. The pars intermedia, which is between the facial and auditory, gives branches to both. The branch given to the auditory accompanies it for a certain distance, and then departs from it to join the geniculate ganglion.

From the geniculate ganglion . . . . . . With the auditory as explained above.

In the Fallopian aqueduct . . . . . . With Meckel’s ganglion by the large superficial petrosal nerve.

At its exit from the stylo-mastoid foramen . . . . . . With the otic ganglion by the small superficial petrosal nerve.

Behind the ear . . . . . . With the sympathetic on the middle meningeal artery by the external superficial petrosal nerve.

On the face . . . . . . With the auricular branch of the pneumogastric.

In the neck . . . . . . With the glosso-pharyngeal.

Opposite the hiatus Fallopii, the gangliform enlargement on the facial nerve communicates with Meckel’s ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal nerve (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylo-mastoid foramen it generally receives a twig of communication from the auricular branch of the pneumogastric.

After its exit from the stylo-mastoid foramen, it sends a twig to the glosso-pharyngeal, another to the pneumogastric nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital nerve behind the ear, on the face with the terminal branches of the three divisions of the fifth, and in the neck with the transverse cervical.

**Branches of Distribution** (Fig. 677).—The branches of distribution of the facial nerves may be thus arranged:

Within the aquaeductus Fallopii . . . . . . Tympanic, to the Stapedius muscle.

At its exit from the stylo-mastoid foramen . . . . . . Chorda tympani.

Posterior Auricular.

Digastric.

Styro-hyoid.

Temporo-facial . . . . . . Temporal.

Malar.

Infraorbital.

Buccal.

Cervico-facial . . . . . . Supramaxillary.

Infra maxillary.
The branches of the two terminal divisions form the parotid plexus (plexus parotideus).

The Tympanic Branch (n. stapedius) (Fig. 677).—The tympanic branch arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The Chorda Tympani (Figs. 671, 676, and 677).—The chorda tympani is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes forward through the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, and over the handle of the malleus, emerging from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the canal of Huguenot (iter chordae posterius). It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is by many regarded as the continuation of the pars intermedia of Wrisberg.

The Posterior Auricular Nerve (n. auricularis posterior) (Figs. 634, 677, and 678).—The posterior auricular nerve arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process and between the mastoid process and the external ear, where it is joined by a filament from the auricular branch of the pneumogastric (Fig. 684), and communicates with the mastoid branch of the great
auricular and with the small occipital. As it ascends between the external auditory meatus and the mastoid process it divides into two branches, the auricular and the occipital branches.

The Auricular Branch supplies the Retrahens auriculam and the small muscles on the cranial surface of the pinna.

The Occipital Branch (ramus occipitalis), the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The Digastric Branch of the Facial Nerve (ramus digastricus).—The digastric branch usually arises by a common trunk with the Stylo-hyoid branch; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve (ramus anastomoticus cum n. glossopharyngeo).

---

Fig. 678.—The nerves of the scalp, face, and side of the neck.

The Stylo-hyoid Branch (ramus stylohyoideus).—The stylo-hyoid branch is a long, slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle.

The Temporo-facial Division (Figs. 677 and 678).—The temporo-facial, the larger of the two terminal branches of the facial, passes upward and forward through
the parotid gland, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infraorbital.

The Temporal Branches (rami temporales) cross the zygoma to the temporal region, supplying the Attraehens and Atttollens auriculam muscles, and join with the temporal branch of the temporo-malar division of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator superciliui muscles, joining with the supraorbital and lachrymal branches of the ophthalmic.

The Malar Branches (rami zygomatici) pass across the malar bone to the outer angle of the orbit. Where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (subcutaneous malae) of the superior maxillary nerve.

The Infraorbital Branches (rami bucales), of larger size than the rest of the malar branches, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The superficial branches run beneath the skin and above the superficial muscles of the face, which they supply; some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infraorbicular and nasal branches of the ophthalmic. The deep branches pass beneath the Zygomatici and the Levator labii superioris, supplying the Levator anguli oris, the Levator labii superioris alaenaque nasi and the small muscles of the nose, and form a plexus, infraorbital plexus, by joining with the branches of the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial.

The Cervico-facial Division.—The cervico-facial division of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, supramaxillary, and inframaxillary.

The Buccal Branches (rami bucales) cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The Supramaxillary or Supramandibular Branch (ramus marginalis mandibulae) passes forward beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The Infraorbital, Infraorbital or Cervical Branch (ramus colli) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahoid region. A branch descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

Surgical Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—i. e., blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in bulbar paralyses. Or (2) it may be paralyzed in its passage through the petrous bone by damage due to middle-ear disease or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as Bell's paralyses. It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.
When the cause is central, the sixth nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electric reactions are the same as in health; whereas, when the paralysis is due to a lesion in the course of the nerve, the reactions of degeneration develop. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; the sense of hearing is affected from paralysis of the Stapedius, but there is not hemiplegia. When the cause of the paralysis is from fracture of the base of the skull, the auditory nerve and the petrosal nerves, which are connected with the intumescentia gangliiformis, are also involved. When the injury to the nerve is after its exit from the stylo-mastoid foramen, all the muscles of expression, except the Levator palpebrae, together with the posterior belly of the Digastric and Stylo-hyoid, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the naso-labial furrow; the nostril of the paralyzed side cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator.

The facial nerve is at fault in cases of so-called histrionic spasm, which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level with the middle of the mastoid process. When found, the nerve may be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve. In facial palsy of extracerebral origin it may be advisable to expose the nerve, cut it across, and anastomose the distal end of the paralyzed nerve to the spinal accessory, or, better, to the hypoglossal nerve (facio-accessory anastomosis or facio-hypoglossal anastomosis). The idea was first proposed by Ballance, and has been put in practice by Ballance and Stewart, Keen, Cushing, Faure, Kennedy and others.

THE EIGHTH OR AUDITORY NERVE (N. ACUSTICUS) (Fig. 679).

The eighth or auditory nerve or Portio Mollis is the special nerve of the sense of hearing, being distributed exclusively to the internal ear. It is soft in texture; hence the name, portio mollis, and is destitute of neurilemma.

The Origin of the Eighth Nerve.—The eighth nerve consists of two sets of fibres, which, although differing in their central connections, are both concerned in the transmission of afferent impulses from the internal ear to the medulla and pons, and from there, by means of new fibres which arise from collections of gray matter in these structures, to the cerebrum and cerebellum. One set of fibres forms the vestibular root, another set forms the cochlear root of the nerve. At its connection with the brain the eighth nerve occupies the groove between the pons and medulla, where it is situated between the restiform body, which is behind, and the seventh nerve, which is in front.

Vestibular, Nexal or Ventral Root (radix vestibularis) (Fig. 613).—The fibres of this root enter the medulla to the inner side of those of the cochlear root, and pass between the restiform body, which is to their outer side, and the inferior root of the fifth, which lies to their inner side. They then divide into an ascending and a descending set. The fibres of the latter end by arborizing around the cells of the internal nucleus, which is situated in the trigonum acustici in the floor of the fourth ventricle. The ascending fibres either end in the same manner or in the external nucleus, which is situated to the outer side of the trigonum acustici and farther from the ventricular floor. It is described as consisting of two parts, an inner, the nucleus of Deiters, and an outer, the nucleus of Rechterew. Some of the axones of the cells of the external nucleus, and possibly also of the internal nucleus, are continued upward through the restiform body to the roof nuclei of the opposite
side of the cerebellum, to which also are prolonged other fibres of the vestibular root without undergoing a relay in the nuclei of the medulla. A second set of fibres from the internal and external nuclei end partly in the tegmentum, while the remainder ascend in the posterior longitudinal bundle to arborize around the nuclei of the oculo-motor nerve.

**Cochlear, Dorsal or Lateral Root (radix cochlearis) (Fig. 613).—**This part of the nerve is placed externally to the vestibular root. Its fibres end in two nuclei, one of which, the *accessory nucleus*, lies immediately in front of the restiform body; the other, the *tuberculum acusticum*, somewhat to its outer side.

The striae acusticae or medullary striae are the axones of the cells of the tuberculum acusticum. They pass backward and inward over the restiform body, and across the floor of the fourth ventricle toward the middle line. Here they dip into the substance of the pons, to end around the cells of the superior olive of the same or opposite side. There are, however, other fibres, and these are both direct and crossed, which do not arborize around the tegmental nuclei, but pass into the lat-

![Distribution of the auditory nerve. (Semidiagrammatic.) (Testut.)](image)

eral fillet. The cells of the accessory nucleus give origin to fibres which pass transversely in the pons and constitute the trapezium. The description given as to the mode of ending of the striae acusticae is applicable to that of the trapezoid fibres—viz., around the cells of the superior olive or of the trapezoid nucleus (which lies ventral to the olive) of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral fillet.

If the further connections of the cochlear nerve of one side, say the left, are considered, it is found that they lie to the outer side of the main sensory tract, the fillet, and are therefore termed the *lateral fillet*. The fibres comprising the left lateral fillet arise in the superior olive or trapezoid nucleus of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are either crossed or uncrossed, the former being the axones of the cells of the right accessory nucleus or of the cells of the right tuberculum acusticum, while the latter are derived from the same cells of the left side. In the upper part of the fillet there is a collection of nerve-cells, the *nucleus of the fillet* (*fila anastomotica*), around
the cells of which some of the fibres arborize, and from the cells of which axones originate to continue upward the tract of the lateral fillet. The ultimate ending of the left lateral fillet is partly in the quadrigeminal bodies of the same or opposite
side, while the remainder of the fibres ascend in the posterior limb of the internal capsule to reach the first and perhaps the second left temporal convolution.

The auditory nerve contains a few afferent fibres which arise in the quadrigeminal bodies, the nucleus of the lateral fillet, trapezoid nucleus, and superior olive.

The auditory nerve after leaving the medulla passes forward across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partly separated by a small artery, the auditory. It then enters the internal auditory meatus with the facial nerve. In the meatus it divides into its two branches, the inferior or cochlear trunk (n. cochleae) and the superior or vestibular trunk (n. vesti biuli). The cochlear trunk is a continuation of the cochlear root, gives branches to the macula acustica of the saccule, and to the ampulla of the posterior semicircular canal, and then passes through the lamina cri-brosa to the labyrinth. The cochlear nerve is distributed to the modiolus and osseous spiral lamina, and is finally distributed to the organ of Corti. The vestibular

![Diagram of the central auditory tract](image)

Fig. 682.—Diagram of the central auditory tract (recurrent system); v.K., ventral nucleus; c.t., trapezoid body; R., raphé; T.K., trapezoid nucleus; o.O., superior olive; T.a., acoustic tuber-cle; S.t.a., acoustic stria; S.K., nucleus of the linniesus; o.V., pre-geminum; n.V., post-geminum; R.I., coterx. (Haller, after Held.)

trunk is a continuation of the vestibular root. In the internal meatus it receives fibres of the pars intermedia and gives a branch to the geniculate ganglion of the facial nerve (Cunningham). It divides into three branches, which pass through the lamina cribrosa and are distributed, one to the macula acustica of the utricle and the ampulla, one to the superior semicircular canal, and one to the external semicircular canal. There is a ganglion on the vestibular nerve called the vestibular ganglion (ganglion vesti bulae), and a ganglion on the cochlear nerve, the ganglion of Corti (ganglion spirale). The fibres of the auditory nerve proper arise in these ganglia; the vestibular fibres in the ganglion vestibulare; the cochlear fibres in the ganglion spirale.

The Auditory Paths (Figs. 680, 681, and 682).—There are two auditory paths, the cochlear or central auditory path and the vestibular path.

The Cochlear Path.—The cochlear path conducts impulses of hearing. Such impulses pass from the organ of Corti to the ganglion of Corti (ganglion spirale) and then by the cochlear fibres to the cochlear nucleus in the medulla. The path from the nucleus to the cortical auditory centre is described as follows.
by Santee.1 Impulses from the cochlear nucleus "run either lateral and dorsal to the restiform body and cross to the opposite side through the acoustic striae and trapezium, or they run medial to the restiform body and enter at once into the trapezium. By either course they reach the lateral fillet, and chiefly the opposite one. The lateral fillets conduct the impulses to the inferior quadrigeminal bodies; the inferior brachia to the internal geniculate bodies, and the acoustic radiation to the third and fourth fifths of the superior temporal and to the transverse temporal gyri of the cerebrum."

The Vestibular Path.—The vestibular path conducts impulses of equilibrium. Impulses from the semicircular canals, utricle and saccule pass by way of the vestibular nerve to the vestibular nuclei in the floor of the fourth ventricle and a spinal nucleus of undetermined situation. From these nuclei impulses pass to the nuclei in the opposite side of the cerebellum by one of two routes. Either by the opposite medial fillet and fibres of the systems of Flechsig or through the acustico-cerebellar tract and fibres of the vestibular nerve in the restiform body to the opposite cerebellum (nucleus fastigii, nucleus globosus, corpus dentatum, and cerebellar cortex).2 From the cerebellum impulses pass along the superior peduncle to "the red nucleus and optic thalamus of both sides and thence to the cortex. They may excite in the cerebellum impulses of equilibration, which descend to the motor nuclei of spinal nerves in the anterior horns of gray matter by way of the antero-lateral descending cerebellar tracts" (Santee).

Surgical Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, it may be bruised or it may be pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may follow loud explosions of dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

THE NINTH OR GLOSSO-PHARYNGEAL NERVE (N. GLOSSOPHARYNGEUS) (Figs. 683, 684, 685).

The ninth or glossopharyngeal nerve is distributed, as its name implies, to the tongue and pharynx, being the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and tonsil; and the nerve of taste to all parts of the tongue to which it is distributed.

Its superficial origin is by three or four filaments, closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and restiform body (Fig. 683). Its deep origin (Fig. 613) may be traced through the fasciculi of the lateral tract to three different sources: (1) some of the fibres may be traced to a nucleus of gray matter at the lower part of the floor of the fourth ventricle beneath the inferior fovea; (2) others may be traced downward into the funiculus solitarius, a rounded bundle of fibres in the lower part of the medulla, commencing immediately above the decussation of the pyramids (these fibres have not been distinctly traced to cells); (3) a third set of

---

1 Anatomy of the Brain and Spinal Cord.  
2 Santee, loc. cit.
Fig. 684.—Plan of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. (After Flower.)
fibres takes origin from the cells of the nucleus ambiguus. This nucleus is situated some distance from the floor of the fourth ventricle and lies slightly internal to the inferior fovea. It gives origin to the motor branches of the glossopharyngeal and vagus, and to the bulbar part of the spinal accessory. The real origin of the sensory fibres of the glossopharyngeal must be looked for in the jugular and petrosal ganglia which are developed from the neural crest.

From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheet of the dura mater, external to and in front of the pneumogastric and spinal accessory nerves (Fig. 685). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process of the temporal bone and the muscles connected with it, to the lower border of the Stylo-phyaryngeus muscle. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-phyaryngeus muscle and the Middle constrictor of the pharynx. It then passes beneath the Hyoglossus muscle, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior and smaller is called the jugular ganglion; the inferior and larger, the petrous ganglion or the ganglion of Andersch.

The Superior or Jugular Ganglion (Ganglion Superius n. Glossopharyngei) (Fig. 684).

The superior or jugular ganglion is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The Inferior or Petrous Ganglion (Ganglion Petrosum n. Glossopharyngei) (Figs. 683 and 684).

The inferior or petrous ganglion is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the superior ganglion and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glossopharyngeal with the pneumogastric and sympathetic nerves.

**Branches of Communication** (Fig. 684).—The branches of communication are with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one of which passes to the auricular branch of the pneumogastric, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric muscle. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

**Branches of Distribution** (Fig. 684).—The branches of distribution are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The Tympanic Branch or Jacobson's Nerve (n.tympanicus).—The tympanic branch or Jacobson's nerve arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower
opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory. These branches form a tympanic plexus (plexus tympanicus). This plexus gives off (1) the greater part of the small superficial petrosal nerve (Fig. 677); (2) a branch to join the great superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the ear.

The Carotid Branches (n. caroticotympanicus superior and n. caroticotympanicus inferior).—The carotid branches descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric and with branches of the sympathetic.

The Pharyngeal Branches (rami pharyngei) (Fig. 684).—The pharyngeal branches are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric and sympathetic nerves to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The Muscular Branch (ramus stylopharyngeus).—The muscular branch is distributed to the Stylo-pharyngeus muscle.

The Tonsillar Branches (rami tonsillares).—The tonsillar branches supply the tonsil, forming a plexus (circulus tonsillectis) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The Lingual Branches (rami linguales).—The lingual branches are two in number: one supplies the circumvallate papillae and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the posterior one-third of the tongue and communicates with the lingual nerve.

The Gustatory Path.—The impressions of taste reach the glosso-pharyngeal nucleus in the medulla in two ways. From the posterior one-third of the tongue and from the palate they reach the nucleus by the ninth nerve. From the anterior two-thirds of the tongue impulses of taste are conveyed by the chorda tympani and pars intermedia. From the glosso-pharyngeal nucleus gustatory impressions pass by way of the medial fillet to the optic thalamus of the opposite side, and from the optic thalamus through the inferior lamina of the internal capsule to the gyrus hippocampi, where the cortical gustatory centre is situated.

Surgical Anatomy.—Injury may produce hemorrhage about the roots of the nerve. Bergmann reported such a case. The patient died from oedema of the glottis after presenting evidences of disorder of speech and difficulty in swallowing.

THE TENTH OR PNEUMOGASTRIC NERVE (N. VAGUS) (Figs. 683, 684, 685).

The tenth or pneumogastric nerve has a more extensive distribution than any of the other crainal nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres, and the pharynx, oesophagus, stomach, and heart with motor fibres. Its superficial origin (Fig. 683) is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its deep origin (Fig. 613) may be traced through the fasciculi of the medulla to a nucleus of gray matter, the nucleus vagi, at the lower part of the floor of the fourth ventricle beneath the ala cinerea below and continuous with the nucleus of origin of the glosso-pharyngeal. In addition to this a few fibres pass into the funiculus solitarius, and others into the nucleus ambiguus or
accessory vagal nucleus. The real origin of the sensory fibres of the vagus is to be found in the cells of the ganglia on the nerve—viz., the ganglion of the root and the ganglion of the trunk. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium (Fig. 685). In passing through this opening the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating them from the glossopharyngeal, which lies in front (Fig. 685). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the superior ganglion, jugular ganglion, or the ganglion of the pneumogastric; to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarges into a second gangliform swelling, called the inferior ganglion or the ganglion of the trunk of the nerve, through which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The vagus nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and the internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck (Fig. 685). From here the course of the nerve differs on the two sides of the body.

On the right side (Fig. 685) the nerve passes across the subclavian artery between
it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network, the posterior pulmonary plexus (*plexus pulmonalis posterior*), from the lower part of which two cords descend upon the oesophagus, on which tube they divide, forming, with branches from the opposite nerve, the oesophageal plexus (*plexus gulae*); below, these branches are collected into a single cord, which runs along the back part of the oesophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the celiac plexus.

On the left side the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the anterior pulmonary plexus (*plexus pulmonalis anterior*), and along the anterior surface of the oesophagus, where it unites with the nerve of the right side in forming the plexus gulae. It passes to the stomach, distributing branches over the anterior surface of that viscus, some extending over the great cul-de-sac, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The Ganglion of the Root of the Pneumogastric Nerve (Ganglion Jugulare) (Fig. 684).

The ganglion of the root or the jugular ganglion is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its (the ganglion’s) auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The Ganglion of the Trunk of the Pneumogastric Nerve (Ganglion Nodosum) (Fig. 684).

The ganglion of the trunk or the inferior ganglion is a plexiform cord, cylindrical in form, of a reddish color, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting Branches (Fig. 684).—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The branches of the pneumogastric are—

In the jugular fossa

- Meningeal.
- Auricular.
- Pharyngeal.
- Superior laryngeal.
- Recurrent laryngeal.
- Cervical cardiac.
- Thoracic cardiac.
- Anterior pulmonary.
- Posterior pulmonary.
- Oesophageal.
- Gastric.

The Meningeal Branch (*ramus meningeus*).—The meningeal branch is a recurrent filament given off from the ganglion of the root in the jugular foramen. It passes
backward, and is distributed to the dura mater lining the posterior fossa of the base of the skull.

The Auricular Branch or Arnold's Nerve (ramus auricularis) (Fig. 684).—The auricular branch or Arnold's nerve arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aquaeductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial; the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The Pharyngeal Branch (ramus pharyngeus).—The pharyngeal branch, the principal motor nerve of the pharynx, arises from the upper part of the ganglion of the trunk of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory; it passes across the internal carotid artery to the upper border of the Middle constrictor of the pharynx, where it divides into numerous filaments which join with those from the glosso-pharyngeal, the superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus (plexus pharyngeus), from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds around the occipital artery.

The Superior Laryngeal Nerve (n. laryngeus superior) (Figs. 683, 684, and 685).—It is larger than the preceding, and arises from the middle of the ganglion of the trunk of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid artery, where it divides into two branches, the external and internal laryngeal. This nerve is the nerve of sensation of the larynx, and also supplies the crico-thyroid muscle. Exner has pointed out that the superior laryngeal nerve innervates to some extent the muscles supplied by the inferior laryngeal, and this fact explains why division of the inferior laryngeal nerve is not of necessity followed by complete paralysis of the muscles it supplies.

The External Laryngeal Branch of the Superior Laryngeal (ramus externus) (Fig. 685), the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The Internal Laryngeal Branch of the Superior Laryngeal (ramus internus) descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backward, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The Inferior or Recurrent Laryngeal Branch of the Pneumogastric (n. laryngeus inferior) (Figs. 684 and 685).—The inferior or recurrent laryngeal branch, so called from its reflected course, is the motor nerve of the larynx. It arises on
THE TENTH OR PNEUMOGASTRIC NERVE

the right side, in front of the subclavian artery; winds from before backward around that vessel, and ascends obliquely to the side of the trachea, behind the common carotid artery and behind or in front of the inferior thyroid artery. On the left side it arises in front of the arch of the aorta, and winds from before backward around the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerve on each side ascends in the groove between the trachea and oesophagus, and, passing under the lower border of the Inferior constrictor muscle, enters the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx except the Cricothyroid. It communicates with the superior laryngeal nerve and gives off a few filaments to the mucous membrane of the lower part of the larynx.

The recurrent laryngeal, as it winds around the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off oesophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the oesophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The Cervical Cardiac Branches (*rami cardiaci superiores*) (Fig. 684).—The cervical cardiac branches, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The Superior Branches are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The Inferior Branches, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes in front of the arch of the aorta and joins the superficial cardiac plexus.

The Thoracic Cardiac Branches (*rami cardiaci inferiores*) (Fig. 684).—The thoracic cardiac branches, on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inwards, they terminate in the deep cardiac plexus.

The Anterior Pulmonary Branches (Fig. 684).—The anterior pulmonary branches, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus* (*plexus pulmonalis anterior*).

The Posterior Pulmonary Branches (Fig. 684).—The posterior pulmonary branches, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic, and form the *posterior pulmonary plexus* (*plexus pulmonalis posterior*). Branches from both pleuraxes accompany the ramifications of the air-tubes through the substance of the lungs (*rami bronchiales anteriores* and *rami bronchiales posteriores*).

The Oesophageal Branches (*rami oesophagei*).—The oesophageal branches are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *oesophageal plexus* (*plexus gulae*). From this plexus branches are distributed to the back of the pericardium.

The Gastric Branches (*rami gastrici*) (Figs. 684 and 685).—The gastric branches are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach. The right pneumogastric sends branches to the *coeliac plexus* (*rami coeliaci*), to the *splenic plexus* (*rami lienales*), and to the *renal plexus* (*rami renales*). The nerve on the left
Surgical Anatomy.—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of the same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralyzed, we have anaesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both the recurrent nerves are paralyzed, the vocal cords are motionless in the so-called cadaveric position—that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory effort. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite cord crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diphtheria, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by bronchocele; or by cancer of the upper part of the oesophagus, when the paralysis is often unilateral. The nerve may be accidentally divided during the operation for goitre.

It is a well-recognized fact that disease or injury of the vagus may induce serious symptoms. Bruising may cause such symptoms; so may injury of the nerve by a stab, a bullet, or during surgical operations. Either accidental ligation or crushing with clamp forceps is particularly dangerous. Michaux accidentally ligated the vagus, and the patient became comatose and ceased to breathe, but was restored on removing the ligature. Tillmanns, while removing a cancer, accidentally caught and crushed a portion of the nerve in a clamp, and both pulse and respiration ceased. The clamp was removed, the patient was restored with difficulty, and the nerve was sutured. Recovery followed. It thus becomes evident that division of the vagus on one side is not, as was so long taught, a necessarily fatal accident; in fact, it is sometimes undertaken deliberately in removing tumors adherent to the nerve. Division of a nerve which has been long compressed is probably not so dangerous as division of a healthy nerve, as in the former case the opposite vagus has probably assumed some of its colleague's duties. A number of cases of deliberate division have been reported. Twenty-three cases are referred to in the system of surgery by von Bergmann and Mikulicz, and twelve of them died, but in none of the deaths was the removal of the vagus the apparent cause of the fatalitY. The editor of this American edition of "Gray" has seen three cases: One was operated upon by Dr. W. Joseph Hearn, one by Dr. Melvin Franklin, and one by the editor. All three recovered, and not one presented any serious disturbance, although each had hoarseness and weakness of voice.

One would assume that after division of the pneumogastric below the superior laryngeal nerve and above the recurrent laryngeal nerve (the region usually attacked) that there would be paralysis of all the muscles of one side of the larynx, except the crico-thyroid, and widespread aberration evinced by disturbances of the heart, stomach, and lungs. As a matter of fact, this has not been the case. It might be and probably would be the case, were a healthy nerve divided; but the surgeon who deliberately divides the nerve does so during the removal of a tumor which has long made pressure. In most cases there is no change in the pulse or respiration. In some cases dysphagia and pneumonia arise, but they may be due to other causes than pneumogastric injury (the formidable nature and the duration of the operation—the ligation of vessels of large size—the age of the subject).

Laryngeal symptoms, to a greater or less degree, are always noted. The difference in the degree of the palsy is explainable when we recall Exner's statement that the muscles supplied by the recurrent laryngeal also receive some innervation from the superior laryngeal. In fact, Mills points out that a portion of the recurrent laryngeal has been resected without completely paralyzing the muscles supposed to be supplied solely by the recurrent laryngeal. The laryngeal symptoms result from unilateral laryngeal paralysis, in which there is paralysis of the muscles which open the glottis. The voice may be lost or may be hoarse. Usually, after a time, this is, to a great extent, compensated for by the opposite vocal cord, although the voice may always remain weak, and the patient will tire easily on talking. If both pneumogastrics were to be divided death would ensue.
THE ELEVENTH OR SPINAL ACCESSORY NERVE (N. ACCESSORIUS)
(Figs. 683, 684, 685).

The eleventh or spinal accessory nerve consists of two parts: one the accessory part to the vagus, and the other the spinal portion.

The Bulbar or Accessory Part of the Spinal Accessory Nerve.

The bulbar or accessory part is the smaller of the two. It is accessory to the vagus. Its superficial origin (Fig. 683) is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its deep origin (Fig. 613) may be traced to a nucleus of gray matter at the back of the medulla, dorso-lateral to the hypo-glossal nucleus, and extending as far down as the intermedio-lateral tract of the spinal cord. It passes outward to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; it is also connected, in the foramen, with the upper ganglion of the vagus by one or two filaments. It then passes through the foramen (Fig. 685), and becoming again separated from the spinal portion it is continued over the surface of the ganglion of the trunk of the vagus, being adherent to its surface, and is distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric (Fig. 684). Through the pharyngeal branch it probably supplies the muscles of the soft palate. Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves.

The Spinal Portion of the Spinal Accessory Nerve.

The spinal portion is firm in texture. Its superficial origin (Fig. 683) is by several filaments or rootlets from the lateral tract of the cord, as low down as the sixth cervical nerve. Its deep origin (Fig. 613) may be traced to the intermedio-lateral tract of the gray matter of the cord. The rootlets of origin join and form a trunk which ascends in the subdural space between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outward to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen it receives one or two filaments from the accessory portion. At its exit from the jugular foramen it passes into the neck and becomes the external branch (ramus externus) (Figs. 634, 684, and 685). It passes backward, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid muscle. It pierces that muscle, and passes obliquely across the posterior triangle, to terminate in the deep surface of the Trapezius muscle. This nerve gives several branches to the Sterno-mastoid muscle during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the posterior triangle it joins with the second and third cervical nerves, while beneath the Trapezius it forms a sort of plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Surgical Anatomy.—Division of the external branch of the spinal accessory nerve causes paralysis of the Sterno-cleido-mastoid and Trapezius muscles; not absolute paralysis, for these muscles also receive nerves from the cervical plexus. In cases of spasmotic torticollis in which all palliative treatment has failed, division or excision of a portion of the external branch of the spinal accessory nerve has been suggested by Keen. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making
THE TWELFTH OR HYPOGLOSSAL NERVE (N. HYPOGLOSSUS)  
(Figs. 686, 687).

The twelfth or hypoglossal nerve is the motor nerve of the tongue. Its superficial origin is by several filaments, from ten to fifteen in number, from the groove between the pyramidal and olivary bodies of the medulla, in a continuous line with the anterior roots of the spinal nerves. Its deep origin can be traced to a nucleus of gray matter (trigonum hypoglossi) on the floor of the fourth ventricle (Fig. 613).

The filaments of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid
foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and is intimately connected with the pneumogastric nerve (Fig. 687); it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops around the occipital artery, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It passes beneath the tendon of the Digastric, the Stylo-hyoid, and the Mylo-hyoid muscles, lying between the last-named muscle and the Hypo-

![Fig. 687.—Hypoglossal nerve, cervical plexus, and their branches.](image)

glossus (Fig. 687), and communicates at the anterior border of the Hypoglossus with the lingual or gustatory nerve (Fig. 686); it is then continued forward in the fibres of the Genio-hyoglossus muscle as far as the tip of the tongue, distributing branches to its muscular substance.

**Branches of Communication** (Fig. 686).—The branches of communication are—

- Pneumogastric.
- Sympathetic.
- First and Second Cervical Nerves.
- Lingual (gustatory).

The first mentioned takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and the ganglion of the trunk.
of the pneumogastric through the mass of connective tissue which here unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds around the occipital artery.

The communication with the sympathetic takes place opposite the atlas vertebra by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

Branches of Distribution (Fig. 686).—The branches of distribution are—the

- **Meningeal.**
  - **Descendens hypoglossi.**
  - **Thyro-hyoid.**
  - **Muscular.**

Meningeal Branches (Fig. 686).—As the hypoglossal nerve passes through the anterior condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull; these filaments are probably derived from a branch which passes from the first cervical nerve to the hypoglossal nerve.

The Descendens Hypoglossi (ramus descendens) (Figs. 686 and 687).—The descendens hypoglossi, long called the descendens noni, is a long slender branch, which quits the hypo-glossal where it turns around the occipital artery. It consists mainly of fibres which pass to the hypoglossal from the first and second cervical nerves in the above-mentioned communication. It descends in front of or within the sheath of the common carotid artery, giving off a branch to the anterior belly of the Omo-hyoid, and then joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop, the *ansa hypo-glossi*. From the convexity of this loop branches pass to supply the Sterno-hyoid, Sterno-thyroid, and the posterior belly of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves.

The Thyro-hyoid Branch (ramus thyreohyoides) (Fig. 686).—The thyro-hyoid is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The Muscular Branches (Fig. 686).—The muscular branches are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches (*rami linguales*) pass upward into the substance of the organ to supply its intrinsic muscles.

Surgical Anatomy.—A wound in the submaxillary region may injure the hypoglossal nerve and result in motor paralysis of the corresponding half of the tongue. The hypoglossal nerve is an important guide in the operation of ligation of the lingual artery (see page 604). It runs forward on the Hyo-glossus muscle just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyo-glossus muscle.

**THE SYMPATHETIC NERVE (SYMPATHICUS)** (Fig. 688).

The sympathetic nervous system consists of (1) a series of ganglia (*ganglia trunci sympathici*) connected together by a great ganglionic cord, the gangliated cord (*truncus sympathicus*), extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses (*plexus sympathici*) or aggregations of nerves and ganglia, situated in front of
the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous nerve-fibres. These latter are of two kinds: communicating, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and distributory, supplying the internal viscera and the coats of the blood-vessels.

Each gangliated cord may be traced upward from the base of the skull into the cranial cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery and in the cavernous sinus (Fig. 692), and communicates with certain cranial nerves (p. 1073). According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion, the ganglion of Ribes, situated upon the anterior communicating artery. Upon the gangliated cord are ganglia distinguished as cervical, dorsal, lumbar, and sacral, and except in the neck they

Fig. 688.—The sympathetic nerve, reduced in size from Byron Robinson’s life-size drawing of a dissection made by himself.

1.—VIII., cervical nerves; 2 a, 2 h, 1 c, 1 d, brachial plexus; 1, spinal accessory nerve (XI. nerve); 2, hypoglossal nerve (XII. nerve); 3, vagus nerve (X. nerve); 4, descendens ommi nerve; 5, laryngeal nerve; 6, superior cervical ganglion; 7, middle cervical ganglion; 8, 9, inferior cervical ganglion; 10, two superior cardiac nerves; 11, two middle cardiac nerves; 12, two ganglia on 10 and 11; 13, branch connecting the inferior cervical ganglion to phrenic nerve; 14, 1, dorsal nerve; 15, left subclavian artery; 16, carotid artery; 17, right subclavian artery; 18, Wrisberg’s ganglion; 19, a, sympathetic branches to the heart; 19, three inferior cardiac nerves. The phrenic nerve in this subject arose from the III., IV., and V. cervical nerves; 20 to 39, lateral chain of sympathetic ganglia; 40, left recurrent laryngeal nerve; 41, superior splanchic nerve; 42, middle splanchic nerve; 43, inferior splanchic nerve; 44, 45, aortic branches from the lateral chain of ganglia; 45 to 56, intercostal nerve; 57, diaphragmatic ganglion; 58, right vagus nerve; 59, left vagus nerve; 60, nerve joining the vagi; 61, coeliac axis; 62, phrenic artery surrounded by the phrenic plexus, which is connected with the phrenic ganglion (57); 63, 64, abdominal branch (ganglion coeliacum); 65, renal ganglion, I. L., II. L., III. L., IV. L., V. L., lumbar nerves; 66, right superior splanchic nerve; 67, seven nerves passing to the adrenal; 68, rich meshwork of nerves surrounding left renal artery; 69, right renal ganglion; 70, 71, ovarian ganglion; 72, aortic plexus; 73, inferior mesenteric ganglion; 74, hypogastric plexus; 75, 76, 77, pelvic vein (cervico-vaginal ganglion). At 75 branches from the pelvic brain are emitted to rectum, vagina, and bladder. At 76 the branches from the II., III., and IV. sacral nerves join the pelvic brain. At 77 the uterine nerves are emitted to supply the uterus; 78, ovarian nerves; 79, uterine nerves; 80, bladder; 81, vagina; 82, 83, rectum; I. S., II. S., III. S., IV. S., sacral nerves; 84, artery uterina ovarica. The right lumbar lateral chain is not numbered; 85, nerves to levator ani; II. and Hyp., ileo-Lympogastric; I', ileo-inguinal; Ec., external cutaneous; Ac., anterior crural; Obi., Obturator; G. C., genito-inguinal; G. S., great sciatic.
correspond pretty nearly in number to the vertebrae against which they lie. They may be thus arranged:

<table>
<thead>

</tbody>
</table>

In the neck they are situated in front of the transverse processes of the vertebrae; in the dorsal region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebrae; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion, the coccygeal ganglion or ganglion impar (ganglion coccygeum impar) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebrospinal nerves.

The branches of communication between the ganglia (Figs. 689 and 690) are composed of gray nerve-fibres (gray rami communicantes) and white nerve-fibres (white rami communicantes), the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The three great gangliated plexuses (collateral ganglia) are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the cardiac, the solar or epigastric, and the hypogastric plexus. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Smaller or Terminal ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres. There are numerous special ganglia connected with the cranial nerves.

These ganglia have been described in a previous section (see ophthalmic ganglion, otic ganglion, sphenopalatine ganglion, and submaxillary ganglion).

The branches of distribution derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

Structure of the Sympathetic System.—The sympathetic system is not, as was so long taught, an independent system. It receives fibres from the cerebrospinal system and arranges them for distribution to the splanchnic blood-vessels and the viscera. It receives fibres from the viscera and transmits them to the cerebrospinal system, and it transmits fibres by way of the spinal nerves to unstriped muscles, to vessels, and to glands. It is simply an arrangement of spinal nerves to permit of the re-arrangement and transmission of impulses. In order to effect this, the spinal nerves are connected with a series of ganglia, which possess a certain power of government or automatic action. In the sympathetic system non-medullated fibres predominate. The individual nerve-fibres are smaller in diameter than those of the cerebro-spinal system, and the fibres are interrupted by nerve-cells contained in a ganglia chain, known as the gangliated cord, and are also sometimes interrupted in gangliated plexuses and in terminal ganglia. The sympathetic nerves have a notable disposition to form plexuses. It is important to note that not all of the visceral branches of the spinal nerves join the gangliated cord—for instance, the visceral branches of the third and fourth sacral do not. The majority, but not all, of the sympathetic fibres are non-medullated (fibres of
Remak), but in the adult true non-medullated fibres are found only in the sympathetic system. These fibres are of smaller diameter than spinal nerve-fibres, and are prolongations of axones of sympathetic ganglia cells. Each fibre is surrounded by connective-tissue structure which resembles the neurilemma, which contains numerous nuclei, and which is a prolongation of the capsule of a sympathetic cell capsule.

A sympathetic nerve consists of numerous non-medullated and some medullated fibres. The connective tissue which separates the nerve-bundles carries blood-vessels and nervi nervorum, but no lymph vessels.

The sympathetic ganglia contain multipolar cells which are smaller than those of the spinal ganglia. Each cell contains two nuclei, and is surrounded by a delicate capsule of connective tissue. The cell gives off one axone and several short dendrites. The axone is non-medullated when it begins and may remain so or may become medullated. Fibres which take origin from sympathetic axones, the commissural fibre, may pass to an adjacent ganglion cell, may pass toward the centre central fibre or gray ramus communicans, or may pass toward the periphery, peripheral fibre, and reach certain glands, or to unstriped muscle of blood-vessels, intestines, iris, etc. The fibres passing to glands are called secretory fibres.

The dendrites of a sympathetic ganglion cell form arborizations about other ganglion cells. The sympathetic ganglia contain fibres, as well as cells. Some of the fibres are medullated and some are non-medullated, the latter taking origin from the sympathetic ganglion cells, the former being motor and sensory cerebrospinal fibres which have reached the sympathetic by the rami communicantes.¹

¹ Histology and Microscopic Anatomy, by Szymonowicz. Translated and edited by John Bruce MacCallum.
The medullated fibres, the white rami communicantes or the visceral branches of the spinal nerves (Figs. 689 and 690) originate from the anterior divisions of certain spinal nerves. Two groups of them can be recognized, one group coming from the nerves from the first or second dorsal to the second or third lumbar nerves; another group from the second or third lumbar to the third or fourth sacral. The visceral branches of the third and fourth sacral do not join the gangliated cord; the other visceral branches do join it. The fibres of the visceral branches of the spinal nerves are derived from both the anterior and the posterior nerve-roots, but more largely from the anterior than from the posterior. The visceral fibres of the anterior roots are axones of nerve-cells of the spinal cord, and by way of the white rami enter into the sympathetic ganglia. Some of them end and form networks about the
ganglia cells. Others pass up or down and end in an adjacent ganglion. Others pass through a ganglion of the gangliated cord and end in a peripheral ganglion with non-medullated fibres, which take origin from ganglia of the gangliated cord. The fibres of the white ramus which pass through the ganglion and go to the periphery are known as the splanchnic efferent fibres, and constitute the secretory fibres of the splanchnic glands and the motor fibres of the muscular tissue of splanchnic blood-vessels and viscera. The visceral fibres of the posterior nerve-roots aid in the formation of the white rami and arise as axones of nerve-cells in the spinal ganglia on the posterior roots, pass through the ganglia of the sympathetic cord, but do not terminate in them, and leave the ganglion directly to pass through a peripheral ganglion to be distributed to the periphery or ascend or descend to an adjacent ganglion and pass through this to a collateral ganglion, and from that to the periphery. They constitute the splanchnic afferent fibres, the sensory fibres of the viscera.

The non-medullated fibres take origin from the cells of the sympathetic ganglia and are axones of these cells. Some help to form the commissure, which joins a ganglion to adjacent ganglia and end as networks about the cells of an adjacent ganglion. Others run to the periphery and help to form the splanchnic efferent branches. Some pass from the ganglia to the spinal nerve-roots and to the anterior and posterior divisions of the nerves. The latter are the gray rami communicantes (Fig. 690), largely composed of non-medullated but containing some medullated fibres. They give branches to the somatic part of the nerves and not the visceral, and furnish secretory fibres and fibres to unstriated muscle and minute branches to the membranes which enwrap the nerve-roots. The commissures of the gangliated cord are composed of white and gray fibres. The former consist of both splanchnic efferent and splanchnic afferent fibres. The latter are axones from sympathetic ganglion cells, and some of these are truly commissural, but others pass up or down the cord and through a ganglion and become branches which go to the periphery.

From the above it becomes evident that the peripheral branches of the sympathetic contain white fibres, which are composed of splanchnic efferent and splanchnic afferent branches and also contain splanchnic efferent gray fibres. Fig. 690, from Cunningham’s Text-book of Anatomy, exhibits the constitution and connections of the gangliated cord of the sympathetic.

THE GANGLIATED CORD (TRUNCUS SYMPATHICUS).

The Cervical Portion (Pars Cervicalis) of the Gangliated Cord.

The cervical portion of the gangliated cord is to be regarded as a prolongation upward of the primitive sympathetic along the great vessels of the neck (Prof. Cunningham). It is not connected to the cervical spinal nerves by white rami communicantes. It obtains its spinal fibres from the upper dorsal nerves. These fibres ascend in the commissure of the gangliated cord and join the cells of the cervical ganglia. From the cervical ganglia come fibres to the unstriped muscle (veins and arteries of the head, neck, and limbs, and to the skin of the head and neck, secretory fibres to the salivary glands and fibres to the heart). The fibres to the vessels are called vasomotor nerves, and the fibres to the heart are called cardio-motor nerves. In the neck the gangliated cord is situated behind the carotid vessels and upon the muscles in front of the vertebrae, and runs from the root of the neck to the base of the skull, being continuous below with the thoracic gangliated cord and ending above in the carotid plexus. There are usually three ganglia on each side, each of which is distinguished, according to its position, as the superior, middle and inferior cervical ganglion.
The Superior Cervical Ganglion (ganglion cervicale superius) (Figs. 691, 692, and 693).—The superior cervical ganglion, the largest of the three, is about three-
quarters of an inch in length. It is placed opposite the second and third cervical vertebrae. It is of a reddish-gray color, is usually fusiform in shape, is sometimes broad and flattened, and is occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle. It is connected to the middle cervical ganglion by the commissure of the gangliated cord.

Branches (Fig. 693).—The branches of the superior cervical ganglion are central and peripheral.

Central or Communicating Branches.—1. Gray rami communicantes arise in the ganglion and pass to the first, second, third, and fourth cervical nerves. 2. Branches are given off to certain cranial nerves in the neck (Figs. 692 and 693). What is known as the jugular nerve (n. jugularis) (Fig. 693) passes to the ganglion on the trunk of the vagus, a branch from the ganglion passes to the ganglia on the root of the pneumogastric (Fig. 693) and to the petrosal ganglion of the glosso-pharyngeal (Fig. 693), and a branch goes to the hypoglossal (Fig. 693).

Peripheral Branches.—These branches may be divided into superior, internal and anterior.

The Superior Branch of the Superior Cervical Ganglion or the Internal Carotid Branch (n. caroticus internus) (Fig. 692) appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The outer branch, the larger of the two, distributes filaments to the internal carotid artery and forms the internal carotid plexus.

The inner branch also distributes filaments to the internal carotid, and, continuing onward, forms the cavernous plexus.

The Internal Carotid Plexus (plexus caroticus internus) (Figs. 691, 692, and 693).—The carotid plexus is situated on the outer side of the internal carotid artery. Filaments from this plexus occasionally form a small gangliiform swelling on the under surface of the artery, which is called the carotid ganglion. The internal carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the sphenopalatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura mater (Valentin), while in the carotid canal it communicates with Jacobson’s nerve, which is the tympanic branch of the glosso-pharyngeal.

The communicating branches with the sixth nerve (Fig. 693) consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the sphenopalatine ganglion is effected by a branch, the large deep petrosal nerve (Fig. 677), which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the large superficial petrosal from the facial to form the Vidian nerve (Figs. 670, 672, and 677). The Vidian nerve then proceeds along the pterygoid or Vidian canal to the sphenopalatine ganglion. The communication with Jacobson’s nerve is effected by two branches, one of which is called the deep petrosal nerve, and the other the carotico-tympanic nerve; the latter may consist of two or three delicate filaments.

The Cavernous Plexus (plexus cavernosus) (Figs. 692 and 693).—The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella turcica in the cavernous sinus, and is formed chiefly
by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic ganglion, and distributes filaments to the wall of the internal carotid and to the pituitary body. The branch of communication with the third nerve (Fig. 693) joins it at its point of division; the branch to the fourth nerve (Fig. 693) joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve (Fig. 693).

The filament of connection with the ophthalmic ganglion (Figs. 666 and 693) arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

![Diagram of the sympathetic nervous system](image)

**Terminal Branches of the Carotid and Cavernous Plexuses.**—The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine around the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinae, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the **ganglion of Ribes,** which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The so-called **Inferior or Descending Branch of the Superior Cervical Ganglion** communicates with the middle cervical ganglion. It is the commissure of the gangliated cord.

---

1 The existence of this ganglion is doubted by some observers.—Ed. of 15th English edition.
Fig. 633.—Plan of the cervical portion of the sympathetic. (After Flower.)
The Internal Branches of the Superior Cervical Ganglion are three in number—the pharyngeal, laryngeal and superior cardiac nerve.

The pharyngeal branches (rami pharyngei) (Figs. 691 and 693) pass inward to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the pharyngeal plexus (plexus pharyngeus).

The laryngeal branches unite with the superior laryngeal nerve and its branches.

The superior cardiac nerve or the nervus superficialis cordis (n. cardicus superior) (Figs. 691 and 693) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve. The right superior cardiac nerve, at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down it obtains one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion. The left superior cardiac nerve, in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The Anterior Branches of the Superior Cervical Ganglion (nn. carotici externi) (Fig. 693) ramify upon the external carotid artery and its branches, forming around each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external carotid artery (plexus caroticus externus) is connected with the branch of the facial nerve to the Stylo-hyoid muscle; that surrounding the facial artery communicates with the sub-maxillary ganglion by one or two filaments; and that accompanying the middle meningeal artery sends offsets which pass to the otic ganglion and to the geniculate ganglion of the facial nerve and constitute the external superficial petrosal nerve (Fig. 677).

The Middle Cervical or Thyroid Ganglion (ganglion cervical medium) (Figs. 391 and 693).—The middle cervical or thyroid ganglion is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It varies somewhat in position, but in most individuals is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, thyroid ganglion, assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

It communicates above with the superior cervical ganglion and below with the inferior cervical ganglion by means of the commissure of the gangliated cord.

The Central Communicating Branches (Fig. 693).—The central communicating branches are: 1. Gray rami communicantes passing from the ganglion to the anterior divisions of the fifth and sixth cervical nerves. 2. The subclavicular loop or the ansa of Vieussens (ansa subclavia) (Fig. 694) arises from the ganglion, passes
down over the front and under the subclavian artery and runs back to join the inferior cervical ganglion. It gives branches to the artery. In some cases this nerve takes origin from the sympathetic trunk below the ganglion.

The Peripheral Branches.—The peripheral branches are the thyroid and the middle cardiac nerve.

The Thyroid Branches (Fig. 693) are small filaments which accompany the inferior thyroid artery to the thyroid gland, forming the inferior thyroid plexus (plexus thyroideus inferior); they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The Middle or Great Cardiac Nerve (n. cardicus medius) (Figs. 691 and 693), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus. If the middle cervical ganglion is absent, the above-named branches arise from the gangliated cord.

The Inferior Cervical Ganglion (ganglion cervicale inferior) (Figs. 691 and 693).—The inferior cervical ganglion is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and is frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves. It joins the middle ganglion above and the first thoracic ganglion below by the commissural cord, and is usually also joined to the middle ganglion by the subclavian loop.

The Central Communicating Branches.—Its central communicating branches are: 1. Gray rami communicantes passing to the anterior divisions of the seventh and eighth cervical nerves (Fig. 693). 2. The subclavian loop (Fig. 694), which has been previously described and which passes under and in front of the subclavian artery to reach the middle cervical ganglion or the commissural cord.

The Peripheral Branches.—The peripheral branches are: 1. Vascular. The vertebral plexus (plexus vertebralis) (Fig. 693) lies upon the vertebral artery and its branches in the neck and in the cranial cavity. The subclavian plexus (plexus subclavius) (Fig. 693) arises from the subclavian loop, which may be regarded as a branch of the inferior or of the middle ganglion. 2. Cardiac. The inferior or minor cardiac nerve (n. cardicus inferior) (Fig. 693) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

Surgical Anatomy.—The situation of the cervical sympathetic makes wounds of it rare. Thirteen cases of sympathetic traumatic injury were collected by Seeligmuller. In ten cases paralysis existed; in three, irritation. Tumors of the neck may cause irritation or paralysis. In irritation of the sympathetic the corresponding side of the face becomes pale, the pupil dilates, the palpebral fissure widens, and the eyeball protrudes. In many cases there is acceleration of the heart beats. In paralysis of the sympathetic the pupil contracts, the palpebral fissure is narrowed by partial ptosis, the corresponding side of the face reddens, there is an increase in the flow of tears, and recession of the eyeball.

The surgeon occasionally resects the sympathetic. Jonnesco recommends bilateral removal of the superior cervical ganglia for glaucoma, and bilateral removal of all the cervical sympathetic ganglia for epilepsy and for exophthalmic goitre.
The Thoracic Portion (Pars Thoracalis) of the Gangliated Cord (Fig. 695).

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebrae, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs, and are covered by the pleura costalis; the last two ganglia are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebrae. The ganglia are small in size and of a grayish color. The first ganglion, larger than the rest, is of an elongated form and is frequently blended with the last cervical ganglion. They are connected together by cord-like prolongations from the substance. In the thorax each thoracic or dorsal spinal nerve, with occasionally the exception of the first, sends a visceral branch or white ramus communicans to the thoracic gangliated cord (Figs. 693 and 695). As Prof. Cunningham points out,
the white rami "separate into two main streams in relation to the sympathetic
cord. Those of the upper five nerves are, for the most part, directed upward in
the gangliated cord to be distributed through the cervical part of the sympathetic
in the manner already described. The white rami of the lower thoracic nerves
are, for the most part, directed downward in the lower part of the sympathetic
cord, and its branches, to be distributed to the abdomen; at the same time some
of their fibres are directly associated with the supply of certain thoracic viscera—
lungs, aorta, oesophagus."\(^1\) The white rami are composed of splanchnic afferent
fibres and somatic and splanchnic efferent fibres.

Central Communicating Branches.—1. \textit{White rami communicantes} (see above).

2. \textit{Gray rami communicantes} arise from each one of the thoracic ganglia, pass back-
ward with the white rami, and enter into the anterior divisions of the thoracic nerves.

Peripheral Branches (Fig. 693).—1. \textit{Aortic Branches} (Fig. 693) come off from the
first five or six upper ganglia. They send filaments to the aorta and its branches,
to the vertebral bodies, and to the vertebral ligaments. The aortic branches help
to form the \textit{thoracic aortic plexus} (\textit{plexus aorticus thoracalis}). This plexus is com-
pleted by branches from the cardiac plexus.

2. \textit{Pulmonary Branches} (Fig. 693) come off from the third and fourth and some-
times from the first and second ganglia.

3. The Splanchnic Nerves (Figs. 688, 691, and 695).—From the six or seven lower
ganglia and from the commissural cord a number of large white branches arise.
They give filaments to the aorta and unite to form the three splanchnic nerves on
each side. These are named the \textit{great}, the \textit{lesser}, and the \textit{smallest} or \textit{renal splanchnic}.

The \textit{superior} or \textit{great splanchnic nerve} (\textit{n. splanchnicus major}) is of a white
color, firm in texture, and presents a marked contrast to the ganglionic nerves.
It is formed by branches from the thoracic ganglia between the fifth and sixth
and the ninth or tenth, but the fibres in the higher roots may be traced upward
in the sympathetic cord as far as the first or second thoracic ganglion. These
roots unite to form a large round cord of considerable size. It descends obliquely
inward in front of the bodies of the vertebrae along the posterior mediastinum,
perforates the crus of the Diaphragm, and terminates in the \textit{semilunar ganglion of
the solar plexus} (Fig. 695), distributing filaments to the \textit{renal} and \textit{suprarenal plexus}.

The \textit{middle}, \textit{lesser} or \textit{small splanchnic nerve} (\textit{n. splanchnicus minor}) is formed
by filaments from the tenth and eleventh ganglia, and from the cord between them.
It pierces the Diaphragm with the preceding nerve, and joins the \textit{solar plexus}
(Fig. 695). It communicates in the chest with the great splanchnic nerve, and
occasionally sends filaments to the renal plexus.

The \textit{inferior}, \textit{smallest}, \textit{least} or \textit{renal splanchnic nerve} (\textit{n. splanchnicus imus}) arises
from the last thoracic ganglion, and, piercing the Diaphragm, terminates in the
\textit{renal plexus} and lower part of the \textit{solar plexus}. It occasionally communicates with
the preceding nerve (Fig. 688).

A striking analogy appears to exist between the splanchnic and the cardiac
nerves. The cardiac nerves are three in number; they arise from the three cer-
vical ganglia, and are distributed to a large and important organ in the thoracic
cavity. The splanchnic nerves, also three in number, are connected probably
with all the dorsal ganglia, and are distributed to important organs in the abdo-
mental cavity.

The Lumbar Portion (\textit{Pars Lumbalis}) of the Gangliated Cord (Figs. 688, 691).

The lumbar portion of the gangliated cord is situated in front of the vertebral
column along the inner margin of the Psoas muscle. It consists usually of four

\(^1\) Text-book of Anatomy.
ganglia, but there may be as many as eight, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia. Sometimes several ganglia are fused together.

It is connected with the thoracic portion by a thin commissure, which passes back or through the Diaphragm. It is connected with the sacral portion by a commissure which is under the common iliac artery.

The upper lumbar ganglia or the upper portion of the gangliated cord receives white rami communicantes from the first two or three lumbar spinal nerves.

Central Communicating Branches.—Gray rami communicantes pass irregularly from the gangliated cord to the anterior divisions of the lumbar spinal nerves, the gray rami accompanying the white rami.

From the situation of the lumbar ganglia these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebrae, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Peripheral Branches.—Some branches pass inward, in front of the aorta, and help to form the abdominal aortic plexus (plexus aorticus abdominalis) (Fig. 691), which plexus is, however, developed chiefly by filaments from the celiac plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus (plexus hypogastricus) (Fig. 691). Numerous delicate filaments are also distributed to the bodies of the vertebrae and the ligaments connecting them.

Pelvic or Sacral Portion (Pars Sacralis) of the Gangliated Cord (Figs. 688, 691).

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion, the coccygeal ganglion or ganglion impar (ganglion coccygeum impar) (Fig. 691). The commissural cord joins the pelvic portion to the lumbar portion of the gangliated cord. Like the cervical portion and the lower lumbar portion the sacral portion receives no white rami communicantes.

The visceral branches of the third sacral, and usually of the second and fourth sacral spinal nerves, are not connected with the ganglionic cord.

Central Communicating Branches.—Gray rami communicantes, which arise in the sacral ganglia and pass to the anterior divisions of the sacral and coccygeal nerves.

Peripheral Branches.—1. Visceral branches arise from the upper portion of the gangliated cord and pass to the pelvic plexus.

2. Parietal branches communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC (Fig. 688).

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, previously alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.
The Cardiac Plexus (Plexus Cardiacus) (Figs. 688, 691).

The cardiacplexus is situated at the base of the heart, and is divided into a superficial part, which lies in the concavity of the arch of the aorta, and a deep part, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The Great or Deep Cardiac Plexus.—The great or deep cardiacplexus, the plexus magnus profundus of Scarpa, is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the inferior cervical cardiac branch from the left pneumogastric.

The branches from the right side of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonaryplexus, and are then continued onward to form part of the left or anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form a part of the right or posterior coronary plexus.

The branches from the left side of the deep cardiacplexus distribute a few filaments to the superficial cardiacplexus, to the left auricle of the heart, and to the anterior pulmonaryplexus, and then pass on to form the greater part of the posterior coronaryplexus.

The Anterior or Left Coronary Plexus (plexus coronarius cordis anterior).—The anterior or left coronaryplexus is formed chiefly from the superficialcardiacplexus, but receives filaments from the deepcardiacplexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

The Posterior or Right Coronary Plexus (plexus coronarius cordis posterior).—The posterior or right coronaryplexus is chiefly formed by filaments prolonged from the left side of the deepcardiacplexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and itsfilaments are distributed with those vessels to the muscular substance of the ventricles.

The Superficial or Anterior Cardiac Plexus.—The superficial or anterior cardiacplexus lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally also the right) inferiorcervicalcardiac branches of the pneumogastric, and filaments from the deepcardiacplexus. A small ganglion, the cardiac ganglion of Wrisberg (ganglion cardiacum [Wrisbergi]) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficialcardiacplexus forms the chief part of the anterior coronaryplexus, and severalfilaments pass along the pulmonary artery to the left anterior pulmonaryplexus.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Pulmonary Plexus (Plexus Pulmonalis).

The larger posterior pulmonaryplexus is situated back of the root of the lung. It is formed by the pneumogastric nerve and branches from the second, third, and fourth thoracic sympathetic ganglia. It sends branches along the bronchi and
blood-vessels into the lung and some fibres pass to the front of the root of the lung to form the anterior pulmonary plexus. The smaller anterior pulmonary plexus is in front of and above the root of the lung. It is formed on each side by the fibres from the posterior pulmonary plexus. The left plexus receives branches from the superficial cardiac plexus. The anterior plexus supplies the structures of the root of the lung.

**The Oesophageal Plexus (Plexus Oesophageus).**

The oesophageal plexus is in the posterior mediastinum and surrounds the oesophagus. It is formed by the pneumogastric nerves which have come from the posterior pulmonary plexuses, and by fibres from the great splanchnic nerve and ganglion. The oesophageal plexus is usually considered as a portion of the pneumogastric nerve (p. 1061).
The Epigastric or Solar Plexus (Plexus Coeliacum) (Figs. 688, 691, 696, 697).

The epigastric or solar plexus supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the pancreas.
and the lesser peritoneal cavity and in front of the aorta and crura of the Diaphragm. It surrounds the celiac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great, the small and the least splanchnic nerves of both sides, and some filaments from the right pneumogastric nerve. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two semilunar ganglia (ganglia coeliaca) (Figs. 688, 696, and 697), which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large, irregular, ganglioniform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

- Phrenic or Diaphragmatic plexus.
- Suprarenal plexus.
- Renal plexus.
- Spermatic plexus.
- Gastric plexus.
- Celiac plexus.
- Splenic plexus.
- Hepatic plexus.
- Superior mesenteric plexus.
- Aortic plexus.

**The Phrenic Plexus** (plexus phrenicus) (Fig. 696).—The phrenic plexus accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion, the diaphragmatic or phrenic ganglion (ganglion phrenicum) (Fig. 697). This ganglion is placed on the under surface of the Diaphragm, near the right suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and hepatic plexus. There is no ganglion on the left side.

**The Suprarenal Plexus** (plexus suprarenalis) (Fig. 696).—The suprarenal plexus is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

**The Renal Plexus** (plexus renalis) (Figs. 696 and 697).—The renal plexus is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others, on both sides, to the spermatic plexuses.

**The Spermatic Plexus** (plexus spermaticus) (Fig. 696).—The spermatic plexus is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

**The Ovarian Plexus** (plexus arteriae ovaricae).—In the female the ovarian plexus is distributed to the ovaries and fundus of the uterus.

**The Celiac Plexus** (plexus coeliacus).—The celiac plexus, of large size, is a direct continuation from the solar plexus; it surrounds the celiac axis and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from
the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The **Gastric or Coronary Plexus** (*plexus gastricus superior*) (Fig. 696) accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The **Spleenic Plexus** (*plexus lienalis*) (Fig. 696) is formed by branches from the celiac plexus, the left semilunar ganglion, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas, the **pancreatic plexus**, and the **left gastro-epiploic plexus**, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The **Hepatic Plexus** (*plexus hepatieus*) (Fig. 696), the largest offset from the celiac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portae.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a **pyloric plexus** accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a **gastro-duodenal plexus**, which subdivides into the **pancreatico-duodenal plexus**, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus. The **gastro-epiploic plexus**, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach, and which is said to anastomose with branches from the splenic plexus, is in reality derived from the splenic plexus. A **cystic plexus**, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The **Superior Mesenteric Plexus** (*plexus mesentericus superior*) (Fig. 696).—The superior mesenteric plexus is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the celiac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., **pancreatic branches** to the pancreas; **intestinal branches**, which supply the whole of the small intestine; and **ileo-colic, right colic, and middle colic branches**, which supply the corresponding parts of the large intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

The **Abdominal Aortic Plexus** (*plexus aortieus abdominalis*) (Figs. 691, 696, and 697).—The abdominal aortic plexus is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The **Inferior Mesenteric Plexus** (*plexus mesentericus inferior*) (Fig. 696) is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., the **left colic and sigmoid plexuses**, which supply the descending and sigmoid flexure of the colon; and the **superior haemorrhoidal plexus** (*plexus haemorrhoidalis superior*), which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus (Plexus Hypogastricus) (Figs. 688, 691, 697).

The hypogastric plexus supplies the visera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries,
and is formed by the union of numerous filaments, which descend on each side from the abdominal aortic plexus and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions, which form the pelvic plexuses.

The Pelvic or Sacral Plexus (Plexus Sacralis).

The pelvic plexus, sometimes called the inferior hypogastric, supplies the viscera of the pelvic cavity, is situated at the side of the rectum in the male, and at the side of the rectum and vagina in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The Inferior Haemorrhoidal Plexus (plexus haemorrhoidalis inferior).—The inferior haemorrhoidal plexus arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior haemorrhoidal plexus.

The Vesical Plexus (plexus vesicalis).—The vesical plexus arises from the forepart of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesiculae seminales and vasa deferentia; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The Prostatic Plexus (plexus prostaticus).—The prostatic plexus is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculae seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the forepart of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forward beneath the pubic arch.

The Small Cavernous Nerve (n. cavernosus penis minor) perforates the fibrous covering of the penis near its roots.

The Large Cavernous Nerve (n. cavernosus penis major) passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpora cavernosa and corpus spongiosum.

The uterine and vaginal plexuses in reality constitute one plexus, the uterovaginal plexus (plexus uterovaginalis).

The Vaginal Plexus arises from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical nerves, a large proportion of spinal nerve-fibres.

The Uterine Plexus arises from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the sides of the organ between the layers of the broad ligaments, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and the Fallopian tube.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.
THE ORGANS OF SPECIAL SENSE.

THE Organs of the Senses are five in number—viz., those of Taste, of Smell, of Sight, of Hearing, and of Touch.

THE TONGUE (LINGUA) (Fig. 698).

The tongue is a very mobile muscular organ, undergoing changes in length and width at every contraction of its muscle. It is the organ of the special sense of taste, and is also an organ of speech, mastication, and deglutition. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw, and when at rest is about three and one-half inches in length. We describe the body, base, apex, dorsum, margin, and inferior surface.

The Body (corpus linguae).—The body forms the great bulk of the organ and is composed of striated muscle.

The Base or Root (radix linguae).—The base or root is directed backward, and connected with the os hyoideum by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds of mucous membrane, the glosso-epiglottic folds; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the mucous membrane.

The Apex or Tip (apex linguae).—The apex or tip is thin and narrow, and is directed forward against the inner surface of the lower incisor teeth.

The Dorsum of the Tongue (dorsum linguae).—The dorsum when the tongue of a living person is at rest is markedly arched from before backward. On the dorsum is a median longitudinal raphe (sulcus medianus linguae). This slight depression terminates posteriorly in the depression known as the foramen caecum (foramen caecum linguae [Morgagni]), from which a shallow-shaped groove, the sulcus terminalis of His, runs outward and forward on each side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, known as the anterior or oral part, forming about two-thirds of its upper surface, is rough and covered with papillae; the posterior third of the dorsum is back of the sulcus terminalis, is known as the posterior or pharyngeal portion, is smoother, and contains numerous muciparous glands and lymphoid follicles.

The Margin of the Tongue (margo lateralis linguae).—The margin of the tongue is free in front of the anterior arch of the palate. Just in front of the arch are several vertical folds, the folia linguae.

The Under or Inferior Surface (facies inferior linguae).—The under or inferior surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles, from its sides the mucous membrane is reflected to the inner surface of the gums; and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the fraenum linguae (frenulum linguae). To each side of the fraenum is a slight fold of the mucous membrane, the plica fimbriata, the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.
Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions (page 398), containing much interposed fat, and supplied by vessels and nerves.

The Mucous Membrane (tunica mucosa linguae).—The mucous membrane invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the fraenum through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes a papillary character.

Structure.—The structure of the mucous membrane of the tongue differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane covering the tongue behind the foramen caecum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles (folliculi linguales), which together constitute what is sometimes termed the lingual tonsil (tonsilla lingualis). Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a

Fig. 698.—Upper surface of the tongue.
funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of mucous glands (glandulae linguales). The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the muscular tissue, and covered with minute eminences, the papillae of the tongue. It consists of a layer of connective tissue, the corium or mucosa, supporting numerous papillae, and covered, as well as the papillae, with epithelium.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be readily demonstrated by maceration or boiling, when it can be easily detached entire; it is much thinner than that of the skin; the intervals between the large papillae are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain coloring matter.

The Corium.—The corium consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels (Fig. 699) and nerves from which the papillae are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

The Papillae of the Tongue (papillae linguales) (Figs. 698, 699, 700, and 701).—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of the upper surface of the tongue, giving to it its characteristic roughness. The varieties of papillae met with are—the papillae maximae or circumvallate papillae, papillae mediae or fungiforme papillae, papillae minimae, conical or filiforme papillae, and papillae simplices or simple papillae.

The Papillae Maximae or Circumvallate Papillae (papillae vallatae) (Figs. 698, 699, and 700) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, in front of the foramen caecum and sulcus terminalis, forming a row on each side, which, running backward and inward, meet in the middle line, like the two lines of the letter V inverted. Each papilla consists of a projection of mucous membrane from \( \frac{3}{16} \) to \( \frac{1}{16} \) of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillae (Fig. 699), which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa around the papilla, having a circular margin of about the same elevation covered with smaller papillae.
Immediately behind the apex of the V is the foramen caecum, mentioned above. This foramen, according to His, represents the remains of the invagination which forms the median rudiment of the thyroid body, and which for a time opens by a duct, the thyroglossal duct, on to the dorsum of the tongue. It may extend downward toward the hyoid bone. Kanthack, however, disputes this view.¹

The Fungiform Papillae or Papillae Mediae (papillae fungiformes et papillae lenticulares) (Fig. 699), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue, but are found chiefly at its sides and apex. They are easily recognized among the other papillae, by their large size, rounded eminences, and deep-red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and are covered with secondary papillae. Their epithelial investment is very thin.

The Conical or Filiform Papillae or Papillae Minimae (papillae conicae et papillae filiformes) (Fig. 699) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillae circumvallatae, excepting at the apex of the organ, where their direction is transverse. Projecting from their apices are numerous filiform processes or secondary papillae; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillae of mucous membrane generally.

Simple Papillae, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillae. They consist of closely set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

Structure of the Papillae (Figs. 699 and 700).—The papillae apparently resemble in structure the papillae of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found, however, that they are not simple elevations like the papillae of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillae (Todd and Bow- man). In the papillae circumvallatae the nerves are numerous and of large size; in the papillae fungiformes they are also numerous, and terminate in aplexiform network, from which brush-like branches proceed; in the papillae filiformes their mode of termination is uncertain. Buried in the epidermis of the papillae circumvallatae, and in some of the fungiformes, are certain peculiar bodies, called taste-buds² (Fig. 701). Each is flask-like in shape, the broad base resting on the corium, and the neck opening by an orifice, the gustatory pore, between the cells of the epithelium.

¹ Journal of Anatomy and Physiology, 1891.
² These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces, and also on the posterior surface of the epiglottis and anterior surface of the soft palate.—Ed. of 15th English edition.
They are formed by two kinds of cells, supporting cells and gustatory cells. The 
supporting cells are mostly arranged like the staves of a cask, and form an outer 
envelope for the bud. Some, however, are found in the interior of the bud between 
the gustatory cells. The gustatory cells occupy the central portion of the bud; 
they are spindle-shaped, and each possesses a large spherical nucleus near the 
middle of the cell. Until recently the teaching was as follows: The peripheral 
end of the cell terminates as the gustatory pore in a fine, hair-like filament, the 
gustatory hair. The central process passes toward the deep extremity of the bud, 
and there ends in a single or bifurcated varicose filament, which was formerly 
supposed to be continuous with the terminal fibril of a nerve; the investigations 
of Lenhossek and others would seem to prove, however, that this is not so, but 
that the nerve-fibrils after losing their medullary sheaths enter the taste-bud, and 

![Diagram](image_url)

**Fig. 701.**—Taste-buds from the papilla foliata of a rabbit. × 850. (Szymonowicz.)

terminate in a fine extremity between the gustatory cells. Other nerve-fibrils 
may be seen ramifying between the cortical cells and terminating in fine extremi-
ties; these, however, are believed to be nerves of ordinary sensation, and not 
gustatory. It is now not believed that the epithelia of the taste-buds are directly 
connected with the nerve-fibres by long processes. "The latest researches have 
shown that dendrites of sensory neurones (sensory nerves) enter the taste-buds 
and end free in telodendria. The latter surround the neuro-epithelial, and, to 
some extent, the sustentacular cells, their relations depending on contact."¹

**Glands of the Tongue.**—The tongue is provided with mucous and serous glands. 
The mucous glands are similar in structure to the labial and buccal glands. They 
are found especially at the back part, behind the circumvallate papillae, but are 
also present at the apex and marginal parts. In connection with these glands 
special ones have been described by Blandin and Nuhn. They are known as the 
glands of Nuhn and Blandin or apical glands (glandulae linguales anteriores of Nuhn 
and Blandin) (Fig. 702). They are situated near the apex of the tongue on either 
side of the fraenum, and each is covered over by a fasciculus of muscular fibre 
derived from the Stylo-glossus and Inferior lingualis muscles. Each gland is from 
half an inch to nearly an inch long and about the third of an inch broad. It has 
from four to six ducts, which open on the under surface of the apex.

The Serous Glands or Glands of v. Ebner occur only at the back of the tongue in 
the neighborhood of the taste-buds, their ducts opening for the most part into the

fossae of the papillae circumvallatae. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The **Hyo-glossal membrane** is a strong fibrous lamina which is derived from the septum of the tongue and which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the posterior fibres of the Genio-hyo-glossus muscles.

The **Vessels of the Tongue.**—The arteries of the tongue are derived from the lingual, the facial, and ascending pharyngeal. The veins of the tongue open into the internal jugular.

The lingual artery (Fig. 704) on each side passes forward beneath the Hyoglossus muscle and courses to the apex of the tongue, between the Genio-glossus and the Inferior lingual muscles, about one-eighth of an inch from the surface. It divides into the ranine (Fig. 702) and sublingual (Fig. 704). Near the apex a branch is given off from the ranine artery, which penetrates the septum and joins a like branch from the other side. The **dorsalis linguæ** is a branch of the lingual supplying the posterior part of the tongue, and rami from the tonsillar branch of the facial go to the same region: A network of capillary vessels is placed beneath the epithelium.

The **ranine veins** lie to the sides of the fraenum underneath the mucous membrane. Each ranine vein runs backward, superficial to and upon the Hyo-glossus muscle and near to the hypo-glossal nerve. The venae comites of the lingual artery usually join the ranine vein, and the trunk opens into the internal jugular vein, but the vessels may open separately into the jugular (Fig. 445).

The **Muscles of the Tongue.**—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic, which have already been described (pp. 396, 397, 398, 399, and 400).
The Extrinsic come from the Stylo-glossus, Hyo-glossus, Genio-glossus, Palato-glossus, and Chondro-glossus. The Intrinsic muscles are the Superior lingualis (m. longitudinalis superior), the Inferior lingualis (m. longitudinalis inferior), the Transverse lingual (m. transversus linguæ), and the Vertical lingual (m. verticalis linguae). The outer or cortical portion of the tongue is composed chiefly of longitudinal fibres. The central or medullary portion is composed chiefly of vertical and transverse fibres and is divided into two parts by a vertical septum (septum linguae), which is a fibrous structure, beginning at the apex and passing back. As it approaches the back it becomes narrower vertically and broadens out transversely to form the hyo-glossal membrane. The fibrous septum is well displayed by making a vertical section of the tongue.

The Lymphatic Vessels of the Tongue (Fig. 491).—The lymphatic vessels from the anterior half of the tongue pass to the submaxillary lymph glands. Lymph vessels from the posterior half of the tongue are connected with satellite glands on the Hyo-glossus muscle and terminate in the deep cervical glands. The last-named lymph-vessel accompanies the canine vein. The lingual lymphatics arise from a network beneath the epithelium. Across the anterior two-thirds of the tongue there is little or no lymphatic connection between the two sides; in the posterior one-third there is free connection.

The Nerves of the Tongue (Fig. 704).—The nerves of the tongue are five in number in each half; the lingual branch of the inferior maxillary division of the fifth, which is distributed to the papillae at the forepart and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; the chorda tympani, which runs in the sheath of the lingual, is generally regarded as the nerve of taste for the same area; the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillae circumvallatae, and which supplies both sensory and gustatory filaments to this region; the hypo-glossal nerve, which is the motor nerve to the muscular substance of the tongue; and the internal laryngeal branch of the superior laryngeal, which sends some fine branches to the root near to the epiglottis. Sympathetic filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. Some of the nerves end free between the cells of epithelium; others terminate as end organs (Meissner’s corpuscles and the end-bulbs of Krause), and in taste-buds as sensory dendrites.

Surgical Anatomy.—The diseases to which the tongue is liable are numerous, and its surgical anatomy is of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical
cleft have been recorded, and it is occasionally, though much more rarely than is commonly sup-
pomed, the seat of tongue-tie, from shortness of the frenum.

There is, however, one condition which must be regarded as congenital, though not uncom-
monly it does not exhibit the significant changes until a year or two after birth. This is an
enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a
greatly increased development of the lymphatic tissue throughout the tongue (macroglossia). This
is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may
assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression.
The treatment consists in excising a V-shaped portion and bringing the cut surfaces together
with deeply placed silver sutures. Compression has been resorted to in some cases with occa-
sional success, but it is difficult to apply. Acute inflammation of the tongue (acute glossitis),
which may be caused by injury or the introduction of some septic or irritating matter, and it
is attended by great swelling from infiltration of the connective tissue of the tongue; this con-
nective tissue is present in considerable quantity. The great swelling renders the patient
incapable of swallowing or speaking, and may seriously impede respiration. The condition may
eventuate in suppuration and the formation of an acute abscess. Chronic abscess, which has
been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different
appearances in different stages of the disease, to which the terms leucoplasia, psoriasis, and
ichthyosis have been given.

The tongue, being very vascular, is often the seat of naevoid growths, and these have a tendency
to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from
the irritation of jagged teeth, dyspepsia, tuberculosis, syphilis, and cancer. Of these the cancerous
ulcer is the most important, and probably also the most common. The variety is the squamous
epithelioma, which soon develops into an ulcer with an indurated base. It produces great pain,
which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the

![Fig. 704.—Under surface of tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons of England.)](image-url)
Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the écarteur or the scissors. The better method is by the scissors, usually known as Whitehead’s method. The mouth is widely opened with a gag, the tongue is transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossi first divided with a pair of curved blunt scissors. The Palato-glossi are also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells’s forceps. The tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured early in the operation, hemorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward. In cases where the disease is confined to one side of the anterior portion of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. If the posterior portion of the tongue is attacked by cancer the entire tongue must be removed, even if but one side of the organ is apparently involved. The exchange of lymph between the halves of the posterior portion of the tongue makes it certain that the opposite half becomes involved soon after the origin of the disease. Whatever operation is performed for cancer of the tongue, the glands must be removed from both sides of the neck. This is to be done, even if but one side of the tongue is removed. Kocher, after performing a preliminary tracheotomy, removes the tongue from the neck, by an incision taken from near the lobule of the ear, down the anterior border of the Stero-mastoid to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured and a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnold advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth pulled out through the external incision, and removed with the knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with. Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawed through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossi detached from the bone, and the Hyo-glossi divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Adjacent lymph glands can be removed, and if the bone is implicated in the disease, it can also be removed by treecing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By operating with the patient in the Trendelenburg position, the blood is caused to flow away from the air-passages. By the judicious use of iodoform the evil mentioned secondly may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE.

The nose is the peripheral portion of the organ of smell (organon olfactus): by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food. The organ of smell consists of two parts; one external, the outer nose; the other internal, the nasal fossae.
THE OUTER NOSE (NASUS EXTERNUS).

The outer nose is the more anterior and prominent part of the organ of smell. Of a triangular form, it is directed downward, and projects from the centre of the face, immediately above the upper lip. Its summit or root (radix nasi) is connected directly with the forehead. Its inferior part or base (basis nasi) presents two elliptical orifices, the nostrils or anterior nares (nares), separated from each other by an antero-posterior septum, the mobile septum or columna nasi (septum mobile nasi). The margins of the nostrils are provided with a number of stiff hairs or vibrissae, which arrest the passage of foreign substances carried with the current of air intended for respiration. The point (apex nasi) is the free extremity of the nose. The lateral surfaces of the nose form, by their union in the middle line, the dorsum (dorsum nasi), the direction of which varies considerably in different individuals. The portion of the dorsum over the nasal bones is the bridge. Each lateral surface terminates below in a rounded eminence, the wing or ala nasi, which, by its lower margin (margo nasi), forms the outer boundary of the corresponding nostril. Above the ala is a depression, the alar sulcus.

Structure.—The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and is supplied with vessels and nerves.

The Bony Framework.—The bony framework occupies the upper part of the organ; it consists of the nasal bones and the nasal processes of the superior maxillary bones (pp. 104 and 109).

The Cartilaginous Framework (cartilagines nasi) (Figs. 705 and 706).—The cartilaginous framework consists of five pieces, the two upper and the two lower lateral cartilages and the cartilage of the septum.

The Upper Lateral Cartilage (cartilago nasi lateralis) of each side is situated below the free margin of the nasal bone. It is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and continuous with the cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.
The Lower Lateral Cartilage, the Cartilage of the Aperture or the Greater Alar Cartilage (cartilago alaris major) of each side consists of two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of the orifice of the nostril. The portion which forms the inner wall (crus mediale), thicker than the rest, is loosely connected with the corresponding portion of the opposite cartilage, and forms a small part of the columna. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the mobile septum. The part of the cartilage which forms the outer wall (crus laterale) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the sesamoid, accessory quadrate or lesser alar cartilages (cartilagineae alares minores). Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril; the ala being formed by dense cellular tissue covered by skin. In front the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

The Triangular Cartilage of the Septum (cartilago septi nasi) (Figs. 705 and 707) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossae in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages. Below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the superior maxillary bones (Fig. 103).

It may be prolonged backward (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the sphenoidal process (processus sphenoidalis septi cartilaginesi). The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the inner portions of the lower lateral cartilages and by the skin; it is freely movable, and hence is termed the mobile septum (septum mobile nasi).

Along the lower margin of the anterior half of the cartilage of the septum is another cartilage which is attached to the vomer and is known as the vomerine cartilage or cartilage of Jacobson (cartilago vomeronasalis).

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The Muscles of the Nose.—The muscles of the nose are situated beneath the integument; they are (on each side) the Pyramidalis nasi, the Levator labii superiores alaeque nasi, the Dilatator naris, anterior and posterior, the Compressor nasi, the Compressor narium minor, and the Depressor alae nasi. They have been previously described (p. 375).

The Integument covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but the integument of the tip and the alae of
THE ORGANS OF SPECIAL SENSE

the nose is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The Mucous Membrane lining the interior of the nose is continuous with the skin externally and with the mucous membrane which lines the nasal fossae within.

The Arteries of the Outer Nose.—The arteries of the nose are the lateralis nasi from the facial, and the inferior artery of the septum from the superior coronary, which supply the alae and septum, the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infraorbital.

The Veins of the Outer Nose.—The veins of the nose terminate in the facial and ophthalmic.

The Lymphatics of the Outer Nose.—These vessels are shown in Figs. 487, 489, and 490. They empty chiefly into the submaxillary lymph glands.

The Nerves of the Outer Nose.—The nerves for the muscles of the nose are derived from the facial, while the skin receives its branches from the infraorbital, infra-trochlear, and nasal branches of the ophthalmic.

THE NASAL FOSSAE (CAVUM NASI).

The nasal fossae are two irregular cavities situated in the middle of the face, one on each side of the middle line, and extending from before backward. They open in front, when the soft parts are in place, by the two nostrils or anterior nares, and terminate, behind, in the naso-pharynx by the posterior nares.

The Anterior Nares (nares).—The anterior nares are somewhat pear-shaped apertures, each measuring about one inch antero-posteriorly and half an inch transversely at their widest part. The nasal fossae in the dry skull open in front by the anterior nasal aperture (apertura pyriformis).

The Posterior Nares (choanae).—The posterior nares are two oval openings, which are smaller in the living or recent subject than in the skeleton, because they
are narrowed by the mucous membrane. Each measures an inch in the vertical and half an inch in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossae see section on Osteology (p. 143).

Inside the aperture of the nostril is a slight dilatation, the vestibule (vestibulum nasi), which extends as a small pouch, the ventricle, toward the point of the nose. Above and behind the vestibule is surrounded by a prominence (limen nasi). Below the prominence the vestibule is lined with skin; above and behind it the fossa is lined with mucous membrane. The fossa, above and behind the vestibule, has been divided into two parts: an olfactory portion (regio olfactoria), a slit-like cavity, comprising the upper and central part of the septum and probably the superior turbinated bone, and a respiratory portion (regio respiratoria), which comprises the rest of the fossa.

![Diagram of the nasal fossae](image)

**Fig. 709.**—Transverse vertical section of the nasal fossae. The section is made anterior to the superior turbinated bones. (Cryer.)

**Outer Wall** (Figs. 708, 709).—The superior, middle, and inferior meatus (meatus nasi superior, medius and inferior) are described on pages 144 and 145. The sphenoidal air sinus opens into the spheno-ethmoidal recess (recessus sphenethmoidalis), a narrow recess above the superior turbinated bone (Fig. 708). The posterior ethmoidal cells open into the front and upper part of the superior meatus (Fig. 708). On raising or cutting away the middle turbinated bone the outer wall of the middle meatus is fully exposed (Figs. 708 and 709) and presents (1) a rounded elevation, termed the bulla ethmoidalis, opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a deep, narrow, curved groove, in front of the bulla ethmoidalis, termed the hiatus semilunaris, into which the anterior ethmoidal cells
and the antrum of Highmore (sinus maxillaris) open, the orifice of the latter being placed near the level of its roof. The middle meatus is prolonged, above and in front, into the infundibulum (infundibulum ethmoidale), which leads into the frontal sinus. The anterior extremity of the meatus is continued into a depressed area which lies above the vestibule and is named the atrium (atrium meatus medii nasi). The nasal duct opens into the anterior part of the inferior meatus, the opening being frequently overlapped by a fold of mucous membrane, and from the orifice of the duct a groove leads downward and forward.

**The Inner Wall** (Fig. 709).—The inner wall or septum is frequently more or less deflected from the mesial plane (Figs. 101 and 709), thus limiting the size of one fossa and increasing that of the other. Ridges or spurs of bone growing outward from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the nasopalatine recess (recessus nasopalatinus), may be seen. In the septum close to this recess a minute orifice may be discerned; it leads into a blind pouch, the rudimentary organ of Jacobson (organon vomeronasale), which is well developed in some of the lower animals, but is rudimentary in man. The organ is supported by a plate of cartilage, distinct from the cartilage of the septum, the cartilage of Jacobson (p. 1097). The cartilage of Jacobson is to the outer side of the lower edge of the cartilage of the septum. The diverticulum opens anteriorly near the floor of the nose and close by Stenson’s foramen. Just below the opening of the blind pouch is an elevation, the eminence of Jacobson.

**The Mucous Membrane** (membrana mucosa nasi).—The mucous membrane lining the nasal fossae is called the pituitary, from the nature of its secretion; or Schneidarian, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the naso-pharynx through the posterior nares. From the nasal fossae its continuity may be traced with the conjunctiva through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossae it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossae are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstances also the various apertures communicating with the meatuses are considerably narrowed or completely closed. The vestibule is lined by modified skin, and contains hairs (vibrissae) which guard the entrance of the nostril.

**Structure of the Mucous Membrane** (Fig. 710).—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the respiratory portion of the nasal cavity the epithelium is columnar and ciliated. Interspersed among the columnar ciliated cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, which is particularly plentiful in children, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the respiratory portion of the mucous membrane there is an extensive anastomosing plexus of veins, which
in some regions forms a distinct cavernous tissue (*plexus cavernosus concharum*). The cavernous tissue is particularly distinct over the inferior turbinated bones. In the olfactory region the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells.

The Supporting Cells contain oval nuclei, situated in the deeper parts of the cells; the free surface of each cell presents a sharp outline, and its deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the supporting cells are a large number of spindle-shaped cells, the olfactory cells, which consist of a large spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, of which one runs outward between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the olfactory hair; the other or deep process runs inward, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the glands of Bowman (*glandulae olfactoriae*), identical in structure with serous glands.

The Arteries of the Nasal Fossae.—The arteries of the nasal fossae are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the sphenopalatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the inferior artery of the septum, from the superior coronary of the facial; and the infraorbital and alveolar branches of the internal maxillary, which supply the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The Veins of the Nasal Fossae.—The veins of the nasal fossae form a close, cavernous-like network beneath the mucous membrane. This cavernous appearance is especially well marked over the lower part of the septum and over the middle and inferior turbinated bones. Some of the veins pass, with those accompanying the sphenopalatine artery, through the sphenopalatine foramen; and others, through the alveolar branch, to join the facial vein; some accompany the eth-
moidal arteries, and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribiform plate of the ethmoid bone, and the foramen caecum.

The Lymphatics of the Nasal Fossae.—The lymphatics can be injected from the subdural and subarachnoid spaces, and form a plexus in the superficial portion of the mucous membrane. The lymph is drained partly into one or two glands which lie near the great cornu of the hyoid bone and partly into a gland situated in front of the axis.

The Nerves of the Nasal Fossae (Fig. 711).—The nerves are: the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion. The olfactory, the special nerve of the sense of smell, is distributed to the olfactory region, and has been already referred to (p. 1019). The nasal branch of the ophthalmic division of the fifth nerve distributes filaments to the forepart of the septum and outer wall of the nasal fossae. Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinate bone. The Vidian nerve supplies the upper and back part of the septum and superior spongy bone, and the upper anterior nasal branches from the spheno-palatine ganglion have a similar distribution. The naso-palatine nerve supplies the middle of the septum. The larger or anterior palatine nerve supplies the lower nasal branches to the middle and lower spongy bones.

Surgical Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose (saddle nose), the result of syphilitic necrosis, imperfect development of the nasal bones in cases of congenital syphilis, or a lateral deviation of the nose the result of fracture.

The skin over the alae and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. The skin is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as a result of intemperance, are apt to become affected, and the nose becomes reddened, congested, and irregularly swollen. To this condition the term grog-blossom is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed lipomata nasii. Ordinary epithelionea and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. They can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Roux's operation, which was introduced for the cure of ozerna. This operation enables the surgeon to remove any dead bone which may be present in this disease. The cartilaginous framework of the nose is lifted up by an incision made inside the mouth, through the junction.
of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by the aid of reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line: this may be the result of an injury or from some congenital defect in its development; in the latter case the deviation usually occurs along the line of union of the vomer and mesethmoid, and rarely occurs before the seventh year. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossa, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection and may arise from several causes: syphilitic or tuberculous ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hemorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. The most common seat of gelatinous polyps is probably the middle turbinate bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossae. The malignant polypi, both sarcomatous and carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths or nose-stones may sometimes be found in the nasal cavities. They arise from the deposition of phosphate of lime upon either a foreign body or a piece of inspissated secretion. The nasal passages furnish a secretion of their own and receive secretion from other parts (tears and secretions of the accessory sinuses). The nasal cavities contain the ethmoidal labyrinth, the lateral masses of the ethmoid (which form the superior and middle turbinated bones), and the inferior turbinated bones. The nasal cavity is surrounded by three pairs of pneumatic spaces, the accessory sinuses. These are the maxillary sinuses, the frontal sinuses, and the cells of the ethmoidal labyrinth. The lachrymal duct opens into the inferior meatus. Inflammation of the air-cells may follow inflammation of the nasal mucous membrane or bone disease. One set of cells or many may suffer. Suppuration may occur. Pus may be blocked up and retained. Dead bone may form. The most serious conditions may follow (abscess of brain, sinus thrombosis, septicæmia), and an operation is necessary to obtain relief.

THE EYE.

The eyeball or globe (bulbus oculi) (Figs. 712 and 716) is contained in the anterior part of the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to different parts; it is supplied by vessels and nerves, and is additionally protected in front by the orbital margins, eyelids, etc.

The eyeball is embedded in the fat of the orbit, but is partly surrounded by a thin membranous sac, the capsule of Ténon, which isolates it, so as to allow of free movement.

The Fascia or Capsule of Ténon (fascia bulbi [Tenoni]) (Figs. 712 and 713).—The fascia or capsule of Ténon consists of a thin membrane which envelops the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is in contact with the outer surface of the sclerotic, the perisclerotic or supra-
scleral lymph-space only intervening. This lymph-space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of connective tissue which extend between the capsule and the sclerotic. This lymph-space forms a flexible pocket, in which the globe rotates. The capsule of Ténon, with the globe, forms a ball-and-socket joint (Deaver). The capsule is perforated behind by the ciliary vessels and nerves and by the optic nerve, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the muscles which move the eyeball and on to each muscle it sends a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle; that on the inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebrae; that of the
Inferior rectus is attached to the inferior tarsal plate. These two recti, therefore, will exercise some influence on the movements of the eyelids. The expansions from the sheaths of the Internal and External recti are strong, especially the one from the latter muscle, and are attached to the lachrymal and malar bones respectively. As they probably check the action of these two recti, they have been named the internal and external check ligaments.

Lockwood has also described a thickening of the lower part of the capsule of Téson, which he has named the suspensory ligament of the eye. It is slung like a hammock below the eyeball, being expanded in the centre and narrow at its extremities, which are attached to the malar and lachrymal bones respectively.1

The anterior one-third of the globe is covered by the conjunctiva, or mucous membrane, reflected from the inner surfaces of the lids (Fig. 715). A lateral view of the globe shows that it is composed of segments of two spheres of different sizes (Figs. 712, 714, 715, and 716). The anterior segment is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. Between the small, anterior or corneal segment, and the large, posterior or scleral segment, is a shallow and narrow groove, the scleral sulcus (sulcus sclerae). The anterior pole is the centre of the anterior portion of the cornea. The posterior pole is the centre of the posterior portion of the sclerotic. A straight line joining

---

THE ORGANS OF SPECIAL SENSE

these two poles is the sagittal or optic axis \((\text{axis optica})\) (Fig. 714). A line drawn around the eyeball equally distant at all points from the two poles is called the equatorial diameter or the equator (Fig. 714). The plane of the equator divides the globe in an anterior and a posterior hemisphere. Meridians may be drawn from one pole to the other at right angles to the equator. The visual axis \((\text{linea visus})\) (Fig. 714) passes in a straight line from the first nodal point on the cornea to the fovea centralis of the yellow spot on the retina. A nodal point is the point of intersection of convergent rays with the visual axis. The first nodal point is 6.9685 mm.

Fig. 715.—Diagram of a horizontal section of the right eye, showing the upper surface of the lower segment. (Testut.)

behind the summit of the cornea. The axes of the eyeballs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed outward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each nerve enters its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole (Fig. 714). The eyeball measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to nearly an inch, the latter to about nine-tenths of an inch. The diameters in the female are somewhat less than in the male.

The eyeball is composed of three investing tunics and of three refracting media.
THE TUNICS OF THE EYE.

From without inward the three tunics are:

I. Sclerotic Coat and Cornea.
II. Choroid, Ciliary Body, and Iris.
III. Retina.

I. The Fibrous or External Coat: The Sclerotic and Cornea
(Tunica Fibrosa Oculi).

The sclerotic and cornea (Figs. 714, 715, and 716) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, being transparent.

The Sclera or Sclerotic Coat (σκληρός, hard).—The sclera or sclerotic coat has received its name from its extreme density and hardness; it is a firm, unyielding, opaque, fibrous membrane, forming the posterior five-sixths of the outer coat and serving to maintain the form of the globe. It is much thicker behind than in front. Its external surface is of a white color, and is in contact with the inner surface of the capsule of Ténon, a lymph-space intervening; it is quite smooth, except one-quarter of an inch back of the sclero-corneal junction, at the points where the Recti and Obliqui muscles are inserted into it, and its anterior part is covered by the conjunctival membrane (Fig. 744); hence the whiteness and brilliancy of the front of the eyeball. Its inner surface is stained a brown color, marked by grooves, in which are lodged the ciliary nerves and vessels (Figs. 719, 724, and 725); the inner surface of the sclera is loosely connected by three layers of exceed-
ingly fine cellular pigmented tissue (lamina fusca) with the outer surface of the choroid, an extensive lymph-space, the perichoroidal space (spatium perichorioideale) (Figs. 727 and 744) intervening between the sclerotic and choroid. Behind the sclera is pierced by the optic nerve (n. opticus), and is continuous with the fibrous sheath of the nerve, which is derived from the dura mater (Fig. 721). At the point where the optic nerve passes through the sclerotic, the lamina fusca is represented by an arrangement of the fibrous tissue which forms a thin network, the cribriform lamina (lamina cribrosa sclerae) (Fig. 731); the minute orifices in this network serve for the transmission of separate bundles of nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings (porus opticus), larger than the rest, occupies the centre of the lamella; it transmits the arteria centralis retinae to the interior of the eyeball (Fig. 731). Around the cribriform lamella are numerous small apertures for the transmission of the ciliary nerves and the short ciliary arteries, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of veins (venae vorticosae) (Fig. 721). In front, the fibrous tissue of the sclerotic is continuous with the substantia propria, the cornea by direct continuity of tissue (Fig. 744), but the opaque sclerotic slightly overlaps the outer surface of the transparent cornea. In the depths of the line of junction between the cornea and the sclera there is a circular canal, the canal of Schlemm (sinus venosus sclerae) (Figs. 716, 723, 727, and 744). This canal receives the sclera veins (Fig. 723) and communicates internally by numerous minute openings in the pectineal ligament of the iris (Fig. 744) with the anterior chamber of the eyeball. These openings are the spaces of Fontana (Fig. 727).

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres (Figs. 720 and 731). These fibres are aggregated into bundles, some of which are arranged in layers having an equatorial direction, but most of which are arranged in layers lying in meridional lines. The sclera is joined to the choroid by three thin layers of loose connective tissue containing pigment cells, the lamina fusca (lamina fasciae sclerae) (Fig. 724). Where the optic nerve passes through the sclera there is a very thin network to represent the lamina fusca. This network is the lamina cribrosa (Fig. 731). The muscles of the eyeball are attached to the sclera (Figs. 715, 716, and 744), and their tendons enter among the bundles of fibrous connective tissue. The conjunctiva covers the anterior portion of the sclera and is attached to it by submucous tissue (Figs. 715 and 727). The sclera yields gelatin on boiling. Its vessels (Figs. 721 and 723) are not numerous, the capillaries being of small size and uniting at long and wide intervals. It obtains arterial blood from the short posterior ciliary and the anterior ciliary arteries. The venous blood is removed by the venae ciliare and the anterior ciliary veins. There are lymph-spaces between the cells which empty into the periscleral (Fig. 712 and p. 1104) and perichoroidal lymph-spaces (Fig. 727). Its nerves are derived from the ciliary nerves (Fig. 719). They lose their medullary sheaths and enter among the bundles of fibrous tissue, but it is not known how they terminate.

The Cornea (Figs. 712, 715, and 721).—The cornea is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost, but not quite, circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from the case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. Usually the curvature is slightly greater in the vertical plane than in the horizontal plane; at its centre than at its periphery, and at its temporal than at its nasal side. The cornea is dense and of uniform thickness throughout;
its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic. The anterior surface is covered with conjunctiva (Fig. 727).

**Structure (Fig. 717).**—The cornea consists of five layers—namely: (1) the anterior or epithelial layer; (2) the anterior elastic layer; (3) the substantia propria; (4) the posterior elastic layer; (5) the posterior or endothelial layer.

![Diagram of the cornea](image)

**Fig. 717.**—Vertical section through the cornea of a newborn child. $\times 200$. (Szymonowicz.)

1. The **Anterior Layer** (*epithelium corneae*) is composed of stratified epithelium and is continuous with the cells of the conjunctiva at the borders of the cornea. There are from five to eight strata of nucleated cells in the anterior layer. The deepest cells are columnar. Above the columnar cells are several layers of polygonal cells, most of which have finger-like processes and are called **prickle cells**. At the surface the cells and nuclei become flat. The anterior epithelial layer prevents the absorption of the fluid of the tears.

2. The **Anterior Elastic or Anterior Limiting Layer** or **Bowman's Membrane** (*lamina elastica anterior*) is less than half the thickness of the layer of stratified epithelium.
It differs in some essential respects from true elastic tissue. It shows evidences of fibrillary structure, and does not have a tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely close interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It ought, therefore, to be regarded as a part of the proper tissue of the cornea.

(3) The Substantia Propria or proper substance of the cornea forms the main thickness of that structure. It is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic. It is composed of about sixty flattened lamellae, superimposed one on another. These lamellae are made up of bundles of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellae at right angles to each other. Fibres, however, frequently pass obliquely from one lamella to the next (fibræ arcuatae).

The lamellae are connected with each other by an interstitial cement-substance, in which are spaces, the corneal spaces, cell spaces or lacunae (Fig. 718). The spaces are stellate in shape, and have numerous offsets or canaliculi (Fig. 718), by which they communicate with each other. Each space contains a cell, the corneal corpuscle (Fig. 718), which resembles in form the space in which it is lodged, but it does not entirely fill it, the remainder of the space containing lymph. In the aged the margin of the cornea becomes opaque gray. This rim is called the arcus senilis, and is due to fat deposit in the lamellae and corneal corpuscles.

(4) The Posterior Elastic Lamina, the Membrane of Descemet, or the Membrane of Demours (lamina elastica posterior), which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of an elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separated from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) “to preserve the requisite permanent correct curvature of the flaccid cornea proper.”

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the spaces of Fontana (spatia
anguli iridis) (Fig. 727). These little recesses communicate with a circular canal in the deeper parts of the corneo-scleral junction. This is the canal of Schlemm (sinus venosus sclerae) (Figs. 716, 723, and 727); it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the ligamentum pectinatum iridis; while others are connected with the forepart of the sclerotic and choroid.

(5) The Posterior Layer or the Corneal Endothelium (endothelium camerae anterioris) lines the aqueous chamber and prevents the absorption of the aqueous humor. It covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of Fontana. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those lining other serous cavities.

Arteries and Nerves.—The foetal cornea contains blood-vessels which pass from the margin almost to the centre. The adult cornea contains no blood-vessels, except at its margin. The capillaries from the sclera and conjunctiva form loops at the corneal margin, and many of these loops enter the cornea for a distance of 1 mm. (Fig. 723). The balance of the cornea is non-vascular and obtains its nourishment from the lymph in the lacunae and canaliculi. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in number (Köhler), forty to forty-five (Waldeyer and Simisch); they are derived from the ciliary nerves; they form the annular plexus (plexus annularis), at the corneal margin, and enter the laminated tissue of the cornea, lose their medullary sheaths, and ramify throughout the substantia propria as the fundamental plexus or the plexus of the stroma. From this deep plexus come perforating fibres (fibræ perforantes), which pass through the anterior elastic lamina and form the subepithelial plexus, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the intra-epithelial plexus. Nerve-fibres from the annular plexus and from the plexus of the stroma come into close relation with the corneal corpuscles.

Dissection.—In order to separate the sclerotic and corneal, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves (Fig. 719) may be seen lying in the loose cellular tissue between the choroid and sclerotic or continued in delicate grooves on the inner surface of the latter membrane.

II. The Choroid, Ciliary Body, and Iris, the Tunica Media, the Uveal Tract (Tunica Vasculosa Oculi) (Figs. 714, 716, 719, 724, 744).

The second or middle tunic of the eye is formed by backward from the choroid, the ciliary body, and the iris.

The choroid is the vascular and pigmentary tunic of the eyeball, investing the posterior five-sixths of the globe, and extending as far forward as the ora serrata of the retina; the ciliary body connects the choroid to the circumference of the iris. The iris is the circular muscular septum, which hangs vertically behind the cornea, presenting in its centre a large rounded aperture, the pupil.

The Choroid (chorioidea).—The choroid is a thin, highly vascular membrane, of a dark-brown or chocolate color, which invests the posterior five-sixths of the
globe, and is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclerotic. It is thicker behind than in front. Externally, it is loosely connected by the lamina fusca with the inner surface of the sclerotic (p. 1108). Its inner surface is attached to the retina.

**Structure** (Fig. 720).—The choroid consists of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus (Fig. 723), and of branched and pigmented cells which lie in connective tissue. There are three layers in the choroid. Named from without inward, they are the lamina suprachorioidea, the choroid proper, and lamina basalis (Fig. 720).

(1) The Lamina Suprachorioidea is on the external surface, that is, the surface next to the sclerotic.

It resembles the lamina fusca of the sclerotic. It is composed of delicate non-vascular lamellae, each lamella consisting of a network of fine elastic fibres, among which are branched pigment-cells. The spaces between the lamellae are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the perisceral space by the perforations in the sclerotic through which the vessels and nerves are transmitted.

(2) The Choroid Proper is internal to the lamina suprachorioidea. In consequence of the small arteries and veins of the choroid proper being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: the outermost (lamina vasculosa), composed of small arteries and veins, with pigment-cells interspersed between them, and the inner (lamina choriocapillaris), consisting of a capillary plexus. The external layer of the choroid proper or the lamina vasculosa consists, in part, of the larger branches of the short
posterior ciliary arteries (Figs. 721, 723, and 725), which run forward between the veins, before they bend inward to terminate in the capillaries; but this layer is formed principally of veins, which have a whirl-like arrangement and empty into four or five large equidistant trunks, the *venae vorticosae* (Figs. 721, 722, and 723), which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Around the veins are lymph-spaces. Interspersed between the vessels are dark star-shaped pigment-cells, the offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary character. The internal layer of the choroid proper consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels (Fig. 723), and is known as the tunic of Ruysch (*lamina chorio-capillaris*). The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous.
with those of the ciliary processes. These two laminae are connected by an *intermediate stratum*, which is destitute of pigment-cells and consists of fine elastic fibres.

On the inner surface of the lamina choriocapillaris is a very thin, structureless, or, according to Kolliker, faintly fibrous membrane, called the *lamina basalis* or *membrane of Bruch*; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

**Tapetum (lucidum).**—This name is applied to the iridescent appearance which is seen in the outer and posterior parts of the choroid of many animals, but not in man.

The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining it from behind.
The Ciliary Body (corpus ciliare) (Fig. 716).—The ciliary body or cyclon joins the choroid to the margin of the iris. It is in reality a process of the choroid or uveal tract and comprises the orbiculus ciliaris, the ciliary processes, and the Ciliary muscle.

The Orbiculus Ciliaris or Annulus Ciliaris (Figs. 724, 726, and 742).—The orbiculus ciliaris is a zone of about one-sixth of an inch in width, directly continuous with the anterior part of the choroid. The lamina basalis presents numerous ridges arranged in a radial manner. The depressions between the ridges are filled with retinal pigment epithelium (Szymonowicz). The orbiculus contains no lamina choriocapillaris.

The Ciliary Processes (processus ciliares) (Figs. 714, 716, 726, and 744).—The ciliary processes are formed by the plaiting and folding inward of the various layers of the choroid—i. e., the choroid proper and the lamina basalis—at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill, the corona ciliaris, behind the iris, round the margin of the lens (Figs. 726 and 744). They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid; the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are the most vascular portion of the eyeball. The processes are covered on their inner surface by two strata of black pigment-cells, which are continued forward from the retina, and are named the pars ciliaris retinae (Figs. 720 and 727). In the stroma of the ciliary processes there are also stellate pigment-cells, which, however, are not so numerous as in the choroid itself.

The Ciliary Muscle or Bowman’s Muscle (m. ciliaris) (Figs. 719, 721, 725, 727, 728, and 729).—The ciliary muscle consists of unstriped fibres; it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the forefront of the choroid, between the choroid and the iris and back of the sclero-corneal junction. It is thickest in front and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular.

The Radiating Fibres (fibrae meridianales [Brucke]) (Figs. 727 and 744), much the more numerous, arise at the point of junction of the cornea and sclerotic, and partly also from the ligamentum pectinatum iridis, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic.
The Circular Fibres (fibrae circulares [Mulleri]) (Figs. 727 and 744) are internal to the radiating ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the "ring muscle" of Muller, and were formerly described as the ciliary ligament. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes.

The Ciliary muscle is admitted to be the chief agent in accommodation—i.e., in adjusting the eye to the vision of near objects. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance. At the present time all agree that the chief element in accommodation is altered curvature of the lens, but there is diversity of opinion as to the manner in which this is accomplished. The view which now prevails is that of Helmholtz. He maintained that in an unaccommodated eye the capsule and suspensory ligament of the lens are tense, and their pressure flattens the anterior surface of the lens, and parallel rays (and rays from objects far off are practically parallel) "are focused on the retina without any sense of effort."

"In accommodation for a near object the meridional or antero-posterior fibres

1 Stewart, Manual of Physiology.
of the ciliary muscle by their contraction pull forward the choroid and relax the suspensory ligament. 'The elasticity of the lens at once causes it to bulge forward till it is again checked by the tension of the capsule.' The pupil is at the same time slightly contracted.

The Iris (iris, a rainbow) (Figs. 716, 719, 721, 723, 724, 727, 728, 729, 730, and 744).—The iris has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humor behind the cornea, and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the pupil (pupilla) (Fig. 730), for the transmission of light. The pupil of a living person varies in size under the influence of light and in efforts at accommodation. In looking at a near object the pupil is small; in looking at a distant object it is large. In light the pupil contracts, in darkness it dilates; hence the pupil is a window which permits light to pass into the interior of the eye. The size of this window depends on the contraction or relaxation of the iris. The iris divides the aqueous chamber (the space between

Fig. 727.—Section of the eye, showing the relations of the cornea, sclerotic, and iris, together with the Ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)

the cornea and lens) into an anterior chamber and a posterior chamber which communicate through the pupil (Figs. 714 and 716). By its circumference or ciliary margin (margo ciliaris) (Figs. 727 and 728) the iris is continuous with the ciliary body, and it is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament (ligamentum pectinatum iridis) (Fig. 744). The pectinate ligament of the iris is derived from the posterior elastic layer of the cornea. This layer divides into numerous fibrillae and some of them reach the iris, and bridge the angle between the cornea and base of the iris (Deaver). The fibrillae which reach the iris constitute the ligament. In this ligament are numerous lymph-spaces, the spaces of Fontana (spatia anguli iridis [Fontanae]) (Fig. 727), and they join the canal of Schlemm to the anterior chamber of the eye. The inner or free edge of the iris forms the margin of the pupil, and is called the pupillary margin (margo pupillaris) (Fig. 728). The surfaces of the iris are flattened, and

1 Stewart, Manual of Physiology.
look forward and backward, the anterior toward the cornea, the posterior toward the ciliary processes and lens. The iris is pigmented and the color of an individual's eyes depends upon this pigment. The anterior surface (facies anterior) (Figs. 728 and 744) of the iris is variously colored in different individuals, and is marked by lines which converge toward the pupil. The posterior surface (facies posterior) (Figs. 726 and 744) is of a deep-purple tint, from being covered by two layers of pigmented, columnar epithelium, which layers are continuous posteriorly with the pars ciliaris retinae. This pigmented epithelium is termed the pars iridica retinae, though it is sometimes named uvea, from its resemblance in color to a ripe grape.

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement-membrane. This layer is continuous with the endothelial layer covering the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. Stroma (stroma iridis).—The stroma consists of fibres and cells. The former are made of fine, delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The Muscular Fibre is involuntary and consists of circular and radiating fibres. The circular fibres (m. sphincter pupillae) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The radiating fibres (m. dilator pupillae) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular, but Grunnert positively demonstrated them. The fibres are very small and are placed between the stroma and the posterior layer of endothelium.

---

1 Von Graefe's Arch. f. Ophthal., Bd. xlvii.
4. Pigment.—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface of the iris and continuous with the pigmented lining of the ciliary processes. The color of the eye in these individuals is due to this coloring-matter showing more or less through the texture of the iris. In the albino even this pigment is absent.

In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the endothelial layers on the front of the iris; to these the dark color of the eye is due.
The Arteries of the Iris (Figs. 723, 725, 727, and 730).—The arteries of the iris are derived from the long posterior ciliary and anterior ciliary and from the vessels of the ciliary processes (see p. 1115). The long posterior ciliary arteries (Figs. 721 and 723), two in number, pass through the sclera, one on the inner and one on the outer side of the optic nerve, and pass forward between the sclera and choroid, and, having reached the attached margin of the iris (Figs. 721 and 730), divide into an upper and a lower branch, and, encircling the iris, anastomose with corresponding branches from the opposite side; into this vascular zone (circulus arteriosus major) (Fig. 744) the anterior ciliary arteries (Fig. 744), from the lacrimal and anterior ciliary from the muscular branches of the ophthalmic, pour their blood. From this zone vessels converge to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (circulus arteriosus minor) in this situation. The veins pass toward the ciliary margin and communicate with the veins of the ciliary processes and of the canal of Schlemm (Figs. 721 and 723).

The Nerves of the Choroid and Iris (Figs. 719, 721, and 729).—The nerves of the choroid and iris are the short ciliary, the ciliary branches of the lenticular ganglion, and the long ciliary from the nasal branch of the ophthalmic division of the fifth. They pierce the sclerotic around the entrance of the optic nerve, and run forward in the perichoroidal lymph-space in which they form a plexus, from which plexus filaments pass to supply the blood-vessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived non-medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the foetus the pupil is closed by a delicate transparent vascular membrane, the membrana pupillaris, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

III. The Tunica Interna or Retina (Figs. 723, 731, 733).

The retina is a delicate nervous membrane, in which the fibres of the optic nerve are spread out and upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward; and, in front, extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the ora serrata (Figs. 723, 742, and 744). Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the para ciliaris retinae and pars iridica retinae already referred to (Figs. 727 and 744). This forward prolongation consists of the pigmentary layer of the retina, together with a stratum of columnar epithelium. The portion back of the ora serrata is called the physiological retina (pars optica retinae) (Fig. 744). The retina is soft, semitransparent, and of a purple tint in the fresh state, owing to the presence of a coloring-material named rhodopsin or visual purple; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the front surface of the posterior part of the retina, corresponding to the visual axis, and at a point in which the sense of vision is most perfect, is an oval yellowish
spot, called, after its discoverer, the **yellow spot of Sømmerring** (*macula lutea*) (Figs. 714 and 733), having a central depression, the **fovea centralis**. The retina in the situation of the fovea centralis is exceedingly thin, and the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name **foramen of Sømmerring** at first given to it. It exists only in man, the quadrumanas, and some saurian reptiles. About one-eighth of an inch (3 mm.) to the nasal side of the yellow spot and one-twenty-fourth of an inch below it, is the point of entrance of the optic nerve, the **optic disk** (*porus opticus*) (Figs. 731 and 733). The circumference of the optic disk is slightly raised so as to form an eminence, the **optic papilla** (*colliculus nervi optici*); the central portion is depressed and is called the **optic cup** (*excavatio papillae nervi optici*). The arteria centralis retinae pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the **blind spot**.

![Diagram of the retina](image)

**Fig. 731.**—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (Toldt.)

**Structure.**—The optical portion of the retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of many layers of nervous structure. These nervous structures are bound together and supported by the **sustentacular fibres**. There are three layers: a **middle** or **neuro-epithelial layer**, an inner layer, and an **outer** or **pigmentary layer**. The neuro-epithelial layer is subdivided into four and the middle layer into six layers; hence the retina consists of eleven layers. The layers from within outward are as follows (Figs. 732, 734, 735, and 736):

1. Inner layer...
2. Neuro-epithelial layer...
3. Outer layer...

---

1. Membrana limitans interna.
2. Layer of nerve-fibres (*stratum opticum*).
3. Ganglionic layer, consisting of nerve-cells.
4. Inner molecular, or plexiform, layer.
5. Inner nuclear layer, or layer of inner granules.
6. Outer molecular, or plexiform, layer.
8. Outer nuclear layer, or layer of outer granules.
10. Jacob's membrane (layer of rods and cones).
11. Pigmentary layer (tapetum nigrum).
1. The Membrana Limitans Interna (Figs. 732, 734, and 735), is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

2. The Layer of Nerve-fibres (Figs. 732, 734, and 735) is formed by the expansion of the optic nerve. This nerve passes through all the other layers of the retina, except the membrana limitans interna, to reach its destination. As the nerve passes through the lamina cribrosa of the sclerotic coat, the fibres of which it is composed lose their medullary sheaths and are continued onward, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, become grouped in bundles, and in many places, according to Michel, arranged in plexuses. Most of the fibres in this layer are centripetal, and are the direct continuations of the
axis-cylinder processes of the cells of the next layer. A few of the fibres are centrifugal, which are axis-cylinders of ganglion-cells within the brain. The centrifugal fibres in the layer of nerve-fibres pass through it and the next succeeding layer to ramify in the inner molecular and inner nuclear layers, where they terminate in enlarged extremities. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The Ganglionic Layer or the Inner Ganglionic Layer (Figs. 732, 734, and 735) consists of a single layer of large ganglion-cells; except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, the rounded internal margin of each cell resting on the preceding layer and sending off an axone which is prolonged as a nerve-fibre into the fibrous layer. From the opposite extremity numerous thicker processes (dendrites) extend into the inner molecular layer, where they branch out into flattened arborizations at different levels. The ganglion-cells vary much in size, and the dendrites of the smaller ones, as a rule,

arborize in the inner molecular layer as soon as they enter it; while the processes of the larger cells ramify close to the inner nuclear layer.

4. The Inner Molecular, the Plexiform or the Inner Reticular Layer (Fig. 732, 734, and 735) is made up of a dense reticulum of minute fibrils, formed by the interlacement of the dendrites of the ganglion-cells with those of the cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibrils a few branched spongioblasts are sometimes embedded.

5. The Inner Nuclear or Inner Granular Layer (Figs. 732, 734, and 735) is made up of a number of closely packed cells, of which there are three different kinds. (1) A large number of oval cells, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They each consist of a large oval body placed vertically to the surface, and containing a distinct nucleus. The protoplasm is prolonged into two processes; one of these passes inward into the inner molecular layer, is varicose in appearance, and ends in a terminal ramification, which is often in close proximity to the ganglion-cells (Fig. 736, 1, c). The outer process passes outward into the outer molecular layer, and there breaks up into a
number of branches. According to Cajal, there are two varieties of these bipolar cells: one in which the outer process arborizes around the knobbed ends of the rod-fibres, and the inner around the cells of the ganglionic layer; these he calls rod-bipolars (Fig. 736, i); the others are those in which the outer process breaks up in a horizontal ramification, in contact with the end of a cone-fibre; these are the cone-bipolars, and their inner process breaks up into its terminal ramifications in the inner molecular layer (Fig. 736, i). (2) At the innermost part of this inner nuclear layer is a stratum of cells, which are named Cajal amacrine cells, from the fact that they have no axis-cylinder process, but they give a number of short protoplasmic processes which extend into the inner molecular layer and there ramify (Fig. 736, i). There are also at the outermost part of this layer some cells, the processes of which extend into and ramify in the outer molecular layer. These are the horizontal cells of Cajal. (3) Some few cells are also found in this layer, connected with the fibres of Müller and will be described with those structures.

6. The Outer Molecular or Outer Reticular Layer or the Plexiform Layer (Figs. 732, 734, and 735) is much thinner than the inner molecular layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the horizontal cells of the preceding layer and the outer processes of the bipolar cells, which ramify in it, forming arborizations around the ends of the rod-fibres and with the branched foot-plates of the cone-fibres.

7. Henle's Fibre Layer is a non-granular layer in the neighborhood of the macula lutea, and is produced by elongations from the inner segments of rod-fibres and cone-fibres.

8. The Outer Nuclear or Outer Granular Layer (Figs. 732, 734, and 735), like the inner nuclear layer, contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane (rod-fibres and cone-fibres) are named rod-granules and cone-granules.

The rod-granules are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of the granule is a fine process; the outer process is continuous with a single rod of Jacob's membrane; the inner passes inward toward the outer molecular layer and terminates in an enlarged extremity.

DESCRIPTION OF FIG. 736.

I. Section of the dog's retina. a. Cone-fibre. b. Rod-fibre and nucleus. c, d. Bipolar cells (inner granules) with vertical ramification of outer processes destined to receive the enlarged ends of rod-fibres. e, f, g, h, i. Small ramifications for ends of cone-fibres. j. Giant bipolar with flattened ramifications. g. Cell sending a neurone or nerve-fibre process to the outer molecular layer. h. Amacrine cell with diffuse arborization in inner molecular layer. i. Nerve-fibrils passing to outer molecular layer. j. Centrifugal fibres passing from nerve-fibre layer to inner molecular layer. k. Nerve-fibril passing into inner molecular layer. l. Ganglion cells.

II. Horizontal or basall cells of the outer molecular layer of the dog's retina. a. Small cell with dense arborization. b. Large cell, lying in inner nuclear layer, but with its processes branching in the outer molecular layer. c. Its horizontal neurone. d. Medium-sized cell of the same character.

III. Cells from the inner part of the ox. a. Rod-bipolar with vertical arborisations. b, c, d, e. Cone-bipolars with horizontal ramification of outer process. b. Cell lying on the outer surface of the outer molecular layer, and ramifying within it. f, j, m. Amacrine cells within the substance of the inner molecular layer.

IV. Neurones or axis-cylinder processes belonging to horizontal cells of the outer molecular layer, one of them, b, ending in a close ramification at a.

V. Nervous elements connected with the inner molecular layer of the ox's retina. a. Amacrine cell, with long processes ramifying in the outermost stratum. b. Large amacrine with thick processes ramifying in second stratum. c. Flattened amacrine with long and fine processes ramifying mainly in the first and fifth strata. d. Amacrine with radiating tuft of fibres destined for third stratum. e. Large amacrine, with processes ramifying in fifth stratum. f, g, h, i. Small amacrines, branching into second stratum. g, h. Other amacrines destined for fourth stratum. a. Small ganglion-cell sending its processes to fourth stratum. b. A small ganglion-cell with ramifications in three strata. c. A small cell ramifying ultimately in first stratum. d. A medium-sized ganglion-cell ramifying in fourth stratum. e. Giant-cell, branching in third stratum. f. A bifrattatred cell ramifying in second and fourth strata.

VI. Amacrines and ganglion-cells from the dog. a. Amacrine with radiating tuft. b. Large amacrine passing to third stratum. c and g. Small amacrines with ramifications in second stratum. f, i. Small amacrine passing to third stratum. d. Amacrine with diffuse arborization. e. Amacrine belonging to fourth stratum. a, d, e, g. Small ganglion-cells ramifying in various strata. b, f, j. Large ganglion-cells showing two different characters of arborization. l. Bifrattatred cell.

VII. Amacrines and ganglion-cells from the dog. a. Amacrine with radiating tuft. b, c, d. Small amacrines ramifying in middle of molecular layer. e, f, h. Small ganglion-cells ramifying in various kinds of arborization. j. A larger cell, similar in character to g, but with longer branch. a, e, l. Giant-cells with thick branches ramifying in the first, second, and third strata. l. Ends of bipolars branching over ganglion-cells.
and is embedded in the tuft into which the outer process of the rod-bipolars break up. In its course it presents numerous varicosities.

The cone-granules, fewer in number than the rod-granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of Jacob's membrane. They do not present any cross-stripping, but contain a pyriform nucleus which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, upon which it rests by a somewhat pyramidal enlargement, from which are given off numerous fine fibrils, which enter the outer molecular layer, where they come in contact with the outer processes of the cone-bipolars.

9. The Membrana Limitans Externa (Figs. 732, 734, and 735), like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

10. Jacob's Membrane or the Layer of Rods and Cones (Figs. 732, 734, and 735) consists of visual cells, and the elements which compose it are of two kinds, rod-cells and cone-cells, the former being much more numerous than the latter.

The rod-cells (Fig. 737) are of nearly uniform size, and arranged perpendicularly to the surface. A rod-cell consists of a rod and a rod-fibre, and the fibre contains the nucleus. The rods are cylindrical and each consists of two portions, an outer segment and an inner segment, which are of about equal length. The segments differ from each other as regards refractation and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained with these reagents, but staining yellowish-brown with osmic acid. The outer portion of each rod is marked by transverse striae, and is made up of a number of thin disks superimposed on one another. It also
The TUNICA INTERNA OR RETINA

exhibits faint longitudinal markings. The inner portion of each rod, at its deeper part where it is joined to the outer process of the rod-granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibres. In most vertebrates the outer portion of the inner segment contains a fibrous body, the ellipsoid of Krause. The visual purple, or rhodopsin, is found only in the outer segments of the rods. At its inner end each rod is prolonged into a very fine fibre, the rod-fibre, which contains a nucleus, and which terminates in the outer nuclear layer, being somewhat enlarged at its termination.

The cone-cells (Fig. 738) are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Each cone-cell consists of two parts, the cone and the cone-fibre.

The cones are shorter than the rods and exhibit an outer and an inner segment.

The outer segment is a short conical process, which, like the outer segment of a rod, presents transverse striae. The inner segment resembles the inner portion of the rods in structure, presenting a superficial striated and deeper granular part; but differs from it in size, being bulged out laterally and presenting a flask shape.

The inner segment of the cone, as does the rod, contains an ellipsoid of Krause. Each cone is prolonged into a cone-fibre, and at the junction of the cone with the fibre is the nucleus of the cone-cell. The cone-fibre passes to the outer nuclear layer, and terminates as an expansion from which very minute fibrils are given off. The chemical and optical characters of the rod-cells and cone-cells are identical.

11. The Pigmentary Layer or Tapetum Nigrum (Fig. 732).—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment-granules. Each cell contains a flattened nucleus in the outer portion of the cell which is free from pigment at this point. These cells are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. The pigment changes its position under the influence of light, and is distributed through the entire cell. In the eyes of albinos, the cells of the pigmented layer are present, but they contain no coloring-matter. In the eyes of many mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the tapetum lucidum.

Supporting Framework of the Retina.—Almost all these layers of the retina are connected together by a supporting framework, formed by the supporting cells or supporting fibres of Müller or radiating fibres, from which the membrana limitans interna et externa are derived. These fibres are found stretched between the two limiting layers (Fig. 732), "like columns between a floor and a roof," and they pass through all the nervous layers except Jacob's membrane. Each commences on the inner surface of the retina by a conical hollow base, which sometimes contains a spheroidal body which stains deeply with haematoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the membrana limitans interna. As they pass through the nerve-fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network, the fibre-baskets, around the rod and cone-fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre. The supporting framework of the retina contains neuroglia cells.

The Path of Light Stimuli.—The stimulus is first received by the rod and cone-cells (the visual cells), and is transmitted to the bipolar cells of the inner nuclear layer and then to the cells of the ganglionic layer, which send fibres by way of the optic nerve to the brain.
Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are wanting as a continuous layer; (2) the ganglionic layer consists of several strata of cells, instead of a single layer; (3) in Jacob’s membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob’s membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer, the pigmentary layer, which is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except Jacob’s membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the Ora Serrata (Fig. 723) the nervous layers of the retina terminate abruptly, and the retina is continued onward as a single layer of elongated columnar cells covered by the pigmentary layer. This prolongation is known as the pars ciliaris retinae (Fig. 727), and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the pars iridica retinae or uvea.

From the description given of the nervous elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve-fibre layers, the majority of the nerve-fibres being formed of the axones of the ganglionic cells. In the inner molecular layer the dendrites of the ganglionic layer interlace with those of the cells of the inner nuclear layer, while in the outer molecular layer a like synopsis occurs between the processes of the inner granules and the rod and cone elements.

The Arteria Centralis Retinae (Figs. 723 and 731) and its accompanying vein, vena centralis retinae, pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately bifurcates into an upper and a lower branch, and each of these again divides into an inner or nasal, and an outer or temporal, branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the arteria centralis retinae do not anastomose with each other—in other words, they are “terminal arteries.” In the foetus, a small vessel passes forward, through the hyaloid canal in the vitreous body, to the posterior surface of the capsule of the lens (Fig. 715).

**THE REFRACTING MEDIA.**

The Refracting media are three, viz.:

Aqueous humor. 
Vitreous body. 
Crystalline lens.

I. The Aqueous Humor (Humor Aqueus).

The aqueous humor completely fills the lymphp space known as the aqueous chamber, the space which is bounded in front by the cornea and behind by the lens and its suspensory ligament and the ciliary body (Fig. 744). The aqueous chamber
is partly divided by the iris into two communicating parts, the anterior and posterior chambers (Figs. 714, 715, and 744). The posterior chamber (cumera oculi posterior) is only a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens, and the ciliary processes. The anterior chamber (cumera oculi anterior) is bounded in front by the cornea and behind by the iris. The external angle of the anterior chamber is bounded by the periphery of the cornea and of the iris. It is called the angle or sinus of the anterior chamber or the filtration angle (angulus iridis). It is by way of the filtration angle that any excess of aqueous humor passes by way of the spaces of Fontana and the canal of Schlemm (Fig. 727) to the anterior ciliary veins and relieves tension. The aqueous humor is small in quantity (scarceley exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

In the adult, these two chambers communicate through the pupil; but in the fetus of the seventh month, when the pupil is closed by the membrana pupillaris, the two chambers are quite separate.

II. The Vitreous Body (Corpus Vitreum) (Figs. 712, 715, 739).

The vitreous body forms about four-fifths of the entire globe. It is composed of a jelly-like tissue containing 98 per cent. water, some salts, and a little albumin, and called the vitreous humor (humor vitreus), connective-tissue fibres, and connective-tissue cells. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the fossa patellaris (fossa hyaloidea) (Fig. 739), for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the hyaloid membrane (membrana hyaloidea), the outside of which is in contact with the membrana limitans interna of the retina. It has been supposed by Hannover, that from its inner surface numerous thin lamellae (stroma vitreum) are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellae cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body; and in the fetus a peculiar fibrous texture pervades the mass, the fibres joining at the numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the canal of Stilling, the hyaloid canal, or the canal of Cloquet (canalis hyaloideus) (Fig. 715), which in the embryonic vitreous humor conveyed the minute vessel from the central artery of the retina to the back of the lens.

The hyaloid membrane encloses the whole of the vitreous humor. In front of the ora serrata it is thickenened by the accession of radial fibres and is termed the zonule of Zinn (zonula ciliaris) (Figs. 742 and 744). It presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they are adherent, as evidenced by the fact that when removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two layers, one of which is thin and lines the fossa patellaris; the other is named the suspensory ligament of the lens; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind
the suspensory ligament there is a sacculated canal, the canal of Petit (spatia zonularia); which encircles the margin of the lens and which can be easily inflated through a fine blow-pipe inserted through the suspensory ligament. It is bounded in front by the anterior layer of the suspensory ligament of the lens, behind by the hyaloidea membrana, and internally by the capsule of the lens. The canal of Petit is a lymph-space. All the spaces of the canal of Petit communicate with the posterior chamber of the eye.

In the foetus, the centre of the vitreous humor presents the hyaloid canal or canal of Stilling, already referred to, which transmits a minute artery, the hyaloid artery, to the capsule of the lens. In the adult, no vessels penetrate its substance, although a lymph channel remains; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. The Crystalline Lens (Lens Crystallina) (Figs.716,723,740,741,742,743,744).

The crystalline lens, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The capsule of the lens (capsula lentis) (Fig. 744) is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens, and is composed in part of cuticular and in part of connective tissue. It is not white fibrous tissue, and is not true elastic tissue (Szymonowicz). Its outer surface is composed of lamella and possesses transverse striations. It rests, behind, in the fossa patellaris in the fore-part of the vitreous body (Fig. 739); in front, it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the posterior chamber of the eye (Fig. 744); and it is retained in its position chiefly by the suspensory ligament of the lens, already described (Fig. 744). The capsule is much thicker in front than behind, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea.

The substance of the lens (substantia lentis) is an epithelial structure and takes origin from the ectoderm. It consists early in development of transparent cylindrical cells, which at a later period become higher at the posterior surface of the lens. Eventually very long cells form; they are known as lens-fibres (fibrae lentis), and are joined by a cement substance. The adult lens consists of lens-fibres, the anterior surface being covered by one layer of cubical epithelial cells, known as lens epithelium (epithelium lentis). This layer extends to the margin of the lens, at which point the cells gain in height and form lens-fibres. The lens-fibres at the margin are nucleated, the others are not. The lens-fibres run as meridians from the anterior surface backward. There is no epithelium on the posterior surface.
In the foetus, a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous around the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the adult no vessels enter its substance.

**Structure.**—The lens is a transparent, biconvex body, the convexity being greater on the posterior than on the anterior surface (Fig. 741). The central points of its anterior and posterior surfaces are known as its **anterior** and **posterior poles** (*polus anterior lentis et polus posterior lentis*) (Fig. 741). It measures from 9 to 10 mm. in the transverse diameter, and about 4 mm. in the antero-posterior. It consists of concentric layers (Fig. 740) of which the external in the fresh state are soft and easily detached (*substantia corticalis*) (Fig. 744); those beneath are firmer, the central ones forming a hardened nucleus (*nucleus lentis*) (Fig. 740). These laminae are best demonstrated by boiling or immersion in alcohol, and consist of minute parallel fibres, which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about $\frac{1}{500}$ of an inch. Faint lines radiate from the anterior and posterior poles to the circumference of the lens. In the adult there may be six or more of these, but in the foetus they are only three in number and diverge from each other at angles of 120° (Fig. 743). On the anterior surface one line ascends vertically and the other two diverge downward and outward. On the posterior surface one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of septa in the lens, along which the ends of the lens-fibres come into
THE ORGANS OF SPECIAL SENSE

Apposition and are joined together by transparent amorphous substance. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens terminate near the peripheral extremity of the plane on the other, and vice versa. Each fibre of the outer layers of the lens contains a nucleus, and these nuclei form a layer, the nuclear layer on the surface of the lens. The nuclear layer is most distinct toward the circumference of the lens.

The changes produced in the lens by age are the following:
In the fetus its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.
In the adult the posterior surface is more convex than the anterior; it is colorless, transparent, and firm in texture.
In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

Arteries of the Globe of the Eye.—The arteries of the globe of the eye are the short posterior ciliary, long posterior ciliary, and anterior ciliary arteries, and the arteria centralis retinae.

---

Fig. 744.—The upper half of a sagittal section through the front of the eyeball. (Toldt.)
The short posterior ciliary arteries (aa. ciliares posteriores breves) (Figs. 721, 723, and 725) are from eight to sixteen in number. They arise from the ophthalmic branch of the internal carotid, pass through the sclerotic coat near the optic nerve, and are distributed to the choroid.

There are two long posterior ciliary arteries (aa. ciliares posteriores longae) (Figs. 721, 723, and 730), one on each side of the optic nerve. They are branches of the ophthalmic. They pass through the sclerotic external to the short ciliary arteries, and extend forward in the choroid. In the ciliary body they form an anastomosis with the anterior ciliary arteries. The anastomosis is known as the circulium iridis major (Figs. 723 and 744). Branches from this circle pass to the iris, and at the periphery of the sphincter of the iris form the circulium iridis minor. The muscular branches and the lachrymal branch of the ophthalmic give off the anterior ciliary arteries (aa. ciliares anteriores), six or eight in number. They pass along tendons of the muscles of the eyeball, reach the sclera, and pass upon the sclera to the corneal margin (Fig. 730). Branches are given off which pass backward to supply the anterior half of the sclera, and which are known as episcleral arteries (aa. episclerales) (Fig. 723). Two branches are given off which pass forward to the conjunctiva bulbii, which are known as the anterior conjunctival arteries (aa. conjunctivales anteriores), which anastomose with the posterior conjunctival branches from the palpebral arteries, and which give branches to the delicate vascular network of the corneal margin which is in the annulus conjunctivae (Spalteholz). Eight or even more branches form the anterior ciliary arteries. They pass through the sclerotic near the sclero-corneal junction, and participate in the formation of the circulium iridis major.

The Veins of the Globe of the Eye (Figs. 721, 722, and 723).—The veins are seen on the outer surface of the choroid. They have a whorl-like formation and empty into four or five large veins, the venae vorticosae. These four, five, or six equidistant venae vorticosae pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve, and empty into the ophthalmic vein. Another set of veins accompany the anterior ciliary arteries, and are known as the anterior ciliary veins (vv. ciliares anteriores). They are derivatives of the venous sinus of the sclera in the canal of Schlemm. They form a circular plexus. They receive vessels, the ciliary muscle, and pass through the sclera close to the corneal margin. Posterior ciliary veins (vv. ciliares posteriores) receive vessels which gather venous blood from the outer surface of the sclera near the optic nerve. The posterior ciliary veins join anteriorly with the venae vorticosae. After emerging from the sclera they receive anterior conjunctival branches, and by means of episcleral veins communicate with the venae vorticosae.

The Lymphatic Passages of the Eyeball.—The conjunctiva contains lymph-vessels. The eyeball contains lymph-spaces, but no lymph-vessels.

There are two sets of lymph-spaces in the eyeball, the anterior and posterior.

The anterior lymph-spaces are the spaces of the cornea, of the iris, of the anterior chamber, and of the posterior chamber.

The lymph from the intralamellar lymph-spaces of the cornea enters the conjunctival lymphatics at the margin of the cornea.

The lymph-spaces of the iris open into the anterior chamber by the crypts of the iris and at the margin of the iris join the spaces of Fontana.

The aqueous humor fills the anterior and posterior chambers, but is furnished by the vessels in the posterior chamber; in part by the vessels of the ciliary body, and in part by the vessels of the posterior surface of the iris. The lymph thus secreted passes by way of the pupil into the anterior chamber, and then is taken up by the spaces of Fontana, the canal of Schlemm, and the anterior ciliary veins.1

1 Deaver’s Anatomy.
The posterior lymph-spaces are the hyaloid canal, the perichoroidal lymph-space, the space of Ténon, the intervaginal space of the optic nerve, and the supravaginal space (Deaver).

The hyaloid canal (Figs. 712 and 715) passes between the posterior surface of the lens and the optic disk. In the embryo the canal holds an artery, the hyaloid artery. During development the artery disappears, but a lymph channel remains. The hyaloid canal opens into the intervaginal space of the optic nerve. Between the sclerotic and the choroid is the perichoroidal lymph-space (Fig. 744). It is around the choroid vessels and the venae vorticosae, and empties into Ténon’s space by means of openings through the sclera about the venae vorticosae.

Ténon’s space (Figs. 712 and 713) is between the sclera and the capsule of Ténon. It receives lymph from the perichoroidal space, and empties into the supravaginal space.

The optic nerve (Fig. 731) has a sheath of dura and a sheath of pia, and between these sheaths is the intervaginal lymph-space. It is divided by a prolongation of the cerebral arachnoid into a subdural space and a subarachnoid space, which empty into the corresponding spaces of the membranes of the brain.

The supravaginal space is between the dural portion of the sheath of the optic nerve and a posterior prolongation of Ténon’s capsule.¹

The Nerves of the Globe of the Eye.—The long ciliary nerves (nn. ciliaris longi), two in number, are derived from the branchial or the ophthalmic ganglion. Both the long and short ciliary nerves perforate the sclera in the neighborhood of the optic nerve (Fig. 721). They pass along the perichoroidal lymph-space, forming a plexus, and send filaments to the choroidal vessels. In front of the Ciliary muscle they form a second plexus, and from it come branches which go to the Ciliary muscle and the muscular fibres and vessels of the iris, sclera, choroid, ciliary body, and iris (Fig. 729). The ciliary nerves supply the cornea. The circular fibres of the iris are innervated by the third nerve and the radiating fibres by the sympathetic.

Surgical Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachetic and ill-nourished. In spite of the absence of blood-vessels, wounds of the cornea usually heal rapidly. A wound which penetrates the cornea opens the anterior chamber, and aqueous humor escapes. An ulcer may also open the anterior chamber. Through a wound or a perforated ulcer the pupillary margin of the iris may prolapse. A trivial injury of the cornea is repaired by transparent tissue. A severe injury is repaired by fibrous tissue, and opacity results. A slight opacity resembling a cloud of gray smoke is called nebula; a more marked white opacity is called leucoma.

In abscess of the cornea pus gravitates between the layers to the lower part of the cornea and the purulent collection assumes a crescentic shape (onyx).

The arcus senilis, seen in the aged, is a condition of haziness or opacity at the corneal margin due to fatty degeneration of the tissue of the cornea. It signifies interference with the blood-supply, because of senile degeneration of adjacent vessels. In cases of granular lids there is a peculiar affection of the cornea, called panus, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term salmon patch is applied. The cornea is richly supplied with nerves, derived from the ciliary nerves, which

¹ For the lymphatic channels of the eyeball see Deaver’s Surgical Anatomy, vol. ii. p. 392.
enter the cornea through the forepart of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic (Fig. 719), and in consequence of the pressure upon them, the cornea, to which they are distributed, becomes anesthetic. When a scar forms on the cornea and the iris becomes adherent, the scar and the iris, and sometimes even the lens, may bulge forward from intraocular tension. This condition is *staphyloma of the cornea*. In conditions of impaired nutrition the cornea may be bulged forward by intraocular pressure. The line of least resistance is a little below the centre of the cornea, and it is bulged forward and strongly curved. This condition is known as *conical cornea*. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In inflammation of the sclerotic and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In inflammation of the iris and ciliary body this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The sclerotic may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. Wounds of the sclerotic, if they do not perforate, usually heal readily. If they extend through the sclerotic they cause diminished tension, are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia. The sclerotic may be weakened by injury, inflammation, etc., and the weakened portion may bulge from intraocular pressure, and even a healthy sclera may bulge from excessive intraocular pressure. According to its situation the lesion is known as *ciliary staphyloma, equatorial staphyloma, or posterior staphyloma*.

One of the functions of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. *Inflammation of the choroid* is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. *Purulent choroiditis* is not confined to the choroid; the retina, the vitreous, and the entire uveal tract become involved, and even other structures may suffer. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which melanotic sarcoma may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured without injury to the other tunices, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hemorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The iris is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the fact that the iris and ciliary body are continuous, and that their vessels communicate, *iritis* is usually associated with *cycloitis*, the disease being called *irido-cyclitis*. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with endothelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*symochia anterior*), or to the capsule of the lens behind (*symochia posterior*). In iritis the lens may become involved, and the condition known as *secondary cataract* may be set up. Tumors occasionally commence in the iris; of these, *eyts*, which are usually congenital and sarcomatous tumors, are the most common and require removal. *Gummata* are not unfrequently found in this situation. In some forms of injury to the eyeball, as from the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The Argyll-Robertson pupil shows no reaction to light, but retains reaction to accommodation and vision remains good.
The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, and is invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

In optic neuritis, papillitis, or choked disk, the ophthalmoscope shows increase in vascularity, and swelling and opacity of the nerve, which extend beyond the disk margins. Optic atrophy is apt to follow. (Fig. 745 shows a normal optic disk.)

The retina may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glionma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. An opacity of the capsule, of the lens, or of both, is known as a cataract. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The filtration area is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The dangerous area of the eye is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

Emmetropia is normal vision. In normal vision the practically parallel light rays from distant objects focus on the retina without effort; divergent rays from near objects are focused on the retina by an effort of accommodation.

Hyperopia or hypermetropia is far-sightedness. In this condition the retina is in front of the principal focus when the eye is at rest. The patient endeavors to correct the failure by constant and tiresome efforts at accommodation. The condition is usually due to inordinate shortness of the axis of the eye, but may be due to loss of the lens, decreased convexity of the refractive surfaces, or lessened refractive power in the refractive media of the eye. It is corrected by the use of convex glasses.
Myopia is near-sightedness. In this condition the rays of light come to a focus in front of the retina, and the patient is subjected to continued eye-strain. It is usually due to too great length of the axis of the eye, but may result from increase in refractive power of refractive media. It is corrected by concave glasses. Sometimes, as a person with hyperopia begins to age, an increased refractive power of the lens causes myopia. The occurrence of myopia in a hyperopic eye is called second sight, and it enables the individual to cease wearing convex glasses.

Exenteration of the contents of the orbit means removal of all the contents except those at the orbital apex. Even the peristomeum is taken away. It is performed for malignant disease.

Evisceration of the eyeball is performed by making a circular incision at the corneal margin and removing the internal and middle coats and the contents of the globe. The sclera is not removed. A glass ball is inserted into the seleral sheath, and the sclera is closed over the ball by vertical stitches, and the conjunctiva is closed over it by transverse stitches. The operation is performed for leukemia or staphyloma of the cornea. An artificial eye (a shell) is placed over the stump when healing is complete.

Enucleation, or excision of the eyeball, differs from exenteration of the orbital contents in the fact that only the eyeball is removed. A circular incision through the ocular conjunctiva is carried around and near to the corneal margin. The conjunctiva and capsule of Ténon are pushed back and the Rectus muscles are clamped and divided back of the clamp. Traction is made upon the globe in a forward and inward direction, and the optic nerve and adjacent structures are cut with scissors from the outer aspect of the globe. The eye is then pulled out of the orbit, and all structures which tend to retain it are divided. The stumps of the Recti muscles are sewed together.

THE APPENDAGES OF THE EYE (TUTAMINA OCULI).

The appendages of the eye include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus—viz., the lachrymal gland, the lachrymal sac, and the nasal duct.

The Eyebrow (Supercilium).

The eyebrows are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. The hairs may entangle foreign bodies and lessen somewhat the force of blows. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercili, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The Eyelid (Palpebra) (Figs. 747, 748).

The eyelids are two thin, movable folds placed in front of the eye, and by closure protecting the eye from injury. The eyelids are composed of skin, superficial fascia, and alveolar tissue, fibres of the Orbicularis palpebrarum muscle, palpebral and orbito-tarsal ligaments, tarsal cartilages, and conjunctiva. The upper lid also contains the Levator labii superioris muscle. In the lids are blood-vessels, lymph-vessels, nerves, and Meibomian glands. There are two lids, the upper (palpebra superior) and the lower (palpebra inferior). The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the Levator palpebrae superioris. Each lid consists of two portions. The part near the orbital margin, "whose groundwork is formed merely by the thin palpebral fascia (septum orbitale)," is called the orbital portion (pars orbitalis). The part in which the tarsus lies is called the tarsal portion (pars tarsalis). Between the two portions in each lid is a sulcus, called, in the upper lid, the superior orbito-palpebral sulcus (sulcus orbitopalpebris superior), and, in the lower lid, the inferior orbito-palpebral sulcus (sulcus orbitopalpebris inferior). When the eyelids are

---

opened an elliptical space, the **interpalpebral slit** (*fissura palpebrarum*), is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called **canthi**.

**The Canthi.**—The **outer canthus** (*angulus oculi lateralis*) is more acute than the inner, and the lids here lie in close contact with the globe; but the **inner canthus** (*angulus oculi medialis*) is prolonged for a short distance inward toward the nose. The two lids are separated at the inner canthus by a triangular space, the **lacus lacrimalis**. At the commencement of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lachrymal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale** (Fig. 751), the commencement of the lachrymal canal (Fig. 750). When the lids are closed a space remains between them and the globe to permit of the flow of tears inward (**rivus lacrimalis**).  

**The Eyelashes** (*cilia*) (Fig. 748).—The eyelashes are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids; those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward. Because of this arrangement the two sets do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of **sebaceous glands** (*glandulae sebaceae*) (Fig. 748) and of a number of glands, **glands of Moll** (*glandulae ciliareae [Moll]*) (Fig. 748), arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat-glands. On the inner surface are the **Meibomian glands** (*glandulae tarsales [Meibomii]*) (Fig. 750). Internal to the openings of the lachrymal canaliculi there are neither lashes nor Meibomian glands.

---

**Structure of the Eyelids** (Fig. 748).—The eyelids are composed of the following structures, taken in their order from without inward:

1. **Integument**, areolar tissue, fibres of the Orbicularis muscle, tarsal plate, and its ligament, Meibomian glands, and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebrae.

2. The **integument** is extremely thin, and continuous at the margin of the lids with the conjunctiva.

3. The **subcutaneous areolar tissue** is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

4. The **fibres of the Orbicularis muscle**, where they cover the palpebrae (*m. ciliaris [Rioland]*) are thin, pale in color, and possess an involuntary action.
The **tarsal plates** are two thin elongated plates of dense connective tissue about an inch in length. They are placed one in each lid, contributing to their form and support.

The **superior tarsal plate, superior tarsus or superior tarsal body** (*tarsus superior*) (Fig. 747), the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebrae is attached.

The **inferior tarsal plate, inferior tarsus or inferior tarsal body** (*tarsus inferior*) (Fig. 747), the smaller of the two, is thinner and of an elliptical form.

The **free or ciliary margin** of these plates is thick, and presents a perfectly straight edge. The **attached or orbital margin** is connected to the circumference of the orbit by the fibrous membrane of the lids, with which it is continuous. The outer angle of each plate is attached to the malar bone by the **external tarsal or external lateral ligament**, or the **external palpebral ligament** or **raphé** (*ligamentum palpebralis*) (Fig. 747). The inner angles of the two plates terminate at the commencement of the lacus lacrimalis; they are attached to the nasal process of the superior maxilla by the **internal tarsal or internal lateral or internal palpebral ligament** or the **tendo oculi** (*ligamentum palpebrale mediale*) (Fig. 747).

The fibrous membrane of the lids constitutes the **orbito-tarsal ligaments** or the **palpebral fasciae**. In reality these so-called ligaments are fasicial expansions situated one in each lid, and are attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebrae, the inferior with the inferior tarsal plate. Externally the superior and inferior ligaments fuse to form the **external tarsal ligament** or **raphé** just referred to; internally they are much thinner, and, becoming separated from the internal tarsal ligament, are fixed to the lachrymal bone immediately behind the lachrymal sac. Together the ligaments form an incomplete septum, the **orbital septum** (*septum orbitale*), which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

**The Meibomian or Tarsal Glands** (*glandulae tarsales [Meibomi]*) (Figs. 748 and 750).—The Meibomian or tarsal glands are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on evertting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are embedded in grooves in the inner
surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a ceal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement-membrane, lined at the mouths of the tubes by stratified epithelium; the deeper parts of the tubes and the secondary follicles are lined by a layer of polyhedral cells. They are thus identical in structure with the sebaceous glands.

The Conjunctiva (Figs. 714, 715, 727, 749).

The conjunctiva is the mucous membrane of the eye. It lines the inner surface of the eyelids, is reflected over the forepart of the sclerotic and cornea, and joins the lids to the eyeball. In each of these situations its structure presents some peculiarities.

The Palpebral Portion (tunica conjunctiva palpebrarum) (Fig. 750).—The palpebral portion of the conjunctiva lines the posterior surface of the lids. It is thick, opaque, highly vascular, and covered with numerous papillae, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid the lachrymal ducts open on its free surface; and at the inner angle of the eye it forms a semilunar fold, the plica semilunaris (plica semilunaris conjunctivae) (Fig. 751). The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the superior and inferior palpebral folds, the former being the deeper of the two. These folds form the superior and inferior conjunctival fornix (Fig. 749).

The Bulbar Portion (tunica conjunctiva bulbi).—Upon the sclerotic the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the cornea the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (p. 1109). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

Fornix of Conjunctiva.—At the point of reflection of each fold of the conjunctiva from the lid on to the globe of the eye a pocket or arch is formed. These arches are termed the fornix conjunctivae (Fig. 749).

Glands of Conjunctiva.—In the conjunctiva there are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle trachoma glands, are found in the conjunctiva, and, according to Stromeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as "identical structures existing in the under eyelid of the ox."

The Nerves of the Conjunctiva.—The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the terminal bulb.

The Caruncula Lacrimalis.—The caruncula lacrimalis is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small
triangular space in this situation, the lacus lachrymalis. It consists of an island of skin containing sebaceous and sweat-glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; it is called the plica semilunaris (Fig. 751). Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the membrana nictitans.

The Lachrymal Apparatus (Apparatus Lacrimalis) (Figs. 750, 751).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The Lachrymal Glands (glandula lacrimalis).—The lachrymal gland is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The forepart of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the inferior lachrymal gland, palpebral portion of the gland, or the accessory gland of Rosenmuller (glandula lacrimalis inferior), the back part of the gland then being called the superior lachrymal gland (glandula lacrimalis superior). The ducts of the lachrymal gland, from six to twelve in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the Lachrymal Gland.—In structure and general appearance the lachrymal resembles the serous salivary glands. In the recent state the cells are so
crowded with granules that their limits can hardly be defined. Each cell contains an oval nucleus, and the cell-protoplasm is finely fibrillated.

The Lachrymal Canaliculi or Canals (Fig. 751) commence at the minute orifices, puncta lacrimalia, on the summit of a small conical elevation, the lachrymal papilla or caruncle (carunculus lacrimalis), seen on the margin of the lids at the outer extremity of the lacus lacrimalis. The superior canal (ductus lacrimalis superior), the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the ampulla. The inferior canal (ductus lacrimalis inferior) at first descends, and then, abruptly changing its course, passes almost horizontally inward to the ampulla. These canals are dense and elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium. The two canals join in a dilatation, the ampulla (ampulla ductus lacrimalis), which empties into the lachrymal sac.

The Lachrymal Sac (saccus lacrimalis) (Fig. 751).—The lachrymal sac is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and the nasal process of the superior maxillary bone. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on its deep surface it is crossed by the Tensor tarsi muscle (Horner's muscle, p. 371), which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the ampulla and lachrymal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.

The Nasal Duct (ductus nasolacrimalis) (Fig. 751).—The nasal duct is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the valve of Hasner (plica lacrimalis [Hasneri]), formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. The membrane in the lachrymal sac and nasal duct is covered with columnar epithelium, as in the nose. This epithelium is in places ciliated.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.
The Lachrymal Apparatus

When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the puncta lacrimalia, the commencement of the lachrymal canals. They are best seen by inverting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle, which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi or internal tarsal ligament. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the tendo oculi, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring ciliares. Such contractions may produce an eversion of the lid known as entropion. Inversion of the lids (entropion) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. In some individuals there is an extra row of eyelashes on the inner margin of the lid, directed toward the cornea (distichiasis). Trichiasis is a condition in which the lashes are directed toward the eye, but there is no inversion of the lid. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as naevi. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the ease when inflammatory products are poured out. The follicles are liable to become inflamed, constituting the disease known as marginal blepharitis, blepharitis ciliaris, or "blear-eye." Irregular or disorderly growth of the eyelashes not frequently occurs, some of them being turned toward the eyeball and producing inflammation and follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary hordeolum or "sty." The Meibomian glands are affected in the so-called "tarsal tumor;" the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The Orbicularis palpebrarum may be the seat of spasm (blepharospasm), either in the form of slight quivering of the lids or repeated twitches, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerves. The Orbicularis may be paralyzed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. As a result there may be ulceration of the cornea, and possibly eventually complete destruction of the eye. In paralysis of the Levator palpebræ superioris there is drooping of the upper eyelid (ptosis) and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. After wounds or burns adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of empyema after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostrils through the lacerated structure into the
connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling on pressure which is characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied by gentle pressure.

The lachrymal gland is occasionally, though rarely, the seat of inflammation (dacryoadenitis), either acute or chronic; it is also sometimes the seat of tumours, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as the result of burns or injury; overflow of tears may in addition result from deviation of the puncta or from chronic inflammation of the lachrymal sac. When there is failure of the lachrymal tubes to drain off the tears and the fluid gathers beneath and flows over the lids, the condition is known as epiphora or stilli-cidium. This latter condition is set up by some obstruction to the nasal duct frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac (dacryocystitis) is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula.

THE EAR (ORGANON AUDITUS).

The organ of hearing is divisible into three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

THE EXTERNAL EAR (AURIS EXTERNA).

The external ear consists of an expanded portion named pinna or auricle, and the auditory canal or meatus. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The Pinna or Auricle (Auricula) (Fig. 752).

The pinna or auricle is attached to the side of the head midway between the forehead and occiput. "Its level is indicated by horizontal lines extending backward from the eyebrows above and from the tip of the nose below." It is of an ovoid form, with its larger end directed upward. Its outer surface is irregularly concave, directed slightly forward. The angle which it bears to the head is called the cephalo-auricular angle. In some cases this angle is almost absent. In others it is nearly a right angle. The pinna of one side may vary in size, shape, and angle from the pinna of the other side. The pinna of a woman is apt to be smaller than that of a man, and is less often deformed. The outer surface of the pinna presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these, names have been assigned. Thus the external prominent rim of the auricle is called the helix. Another curved prominence, parallel with and in front of the helix, is called the antihelix; this bifurcates above and forms the crura, which encloses a triangular depression, the fossa of the antihelix (fossae triangularis [auriculae]). The narrow curved depression between

1 Arthur Hensman in Henry Morris' Human Anatomy.
the helix and antihelix is called the **fossa of the helix** or the **scaphoid fossa** (*scapha*); the antihelix describes a curve around a deep, capacious cavity, the **concha auriculae**, which is partially divided into two parts by the **crus of the helix**, or the commencement of the helix; the upper part is termed the **cymba conchae**, the lower part the **cavum conchae**. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the **tragus**, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (**incisura intertragica**) is a small tubercle, the **antitragus**. Below this is the **lobule** (*lobulus auriculae*), composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna. Sometimes the lobule does not hang freely, but is adherent. Where the helix turns downward a small tubercle, the **tubercle of Darwin** (*tuberculum auriculæ [Darwini]*), is frequently seen. This tubercle is very evident about the sixth month of foetal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys.
The cranial surface of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, e. g., eminentia conchae, eminentia fossae triangularis, etc.

The eminentia conchae and the fossae triangularis are separated by a furrow (sulcus antihelicis transversus), which corresponds to the inferior crus of the antihelix, or groove (sulcus cruris helicis), and upon the eminence there is a vertical ridge, the ponticulus, which indicates the point of insertion of the Retrahens auriculam muscle.

**Structure of the Pinna.**—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal by fibrous tissue.

**The Integument.**—The integument is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

**The Cartilage of the Pinna (cartilago auriculæ) (Fig. 754).**—The cartilage of the pinna consists of one single piece; it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle; thus it does not form a constituent part of the lobule; it is deficient also between the lamina of the tragus and beginning of the crus helix, the notch between (incisura terminalis auris) then being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the spine of the helix (spina helicis), while the lower part of the helix is prolonged downward as a tail-like process, the cauda helicis; this is separated from the antihelix by a fissure, the fissura antitragohelicina. The fissures of Santorini are usually two in number: one in the substance of the tragus, which partially separates the different parts, and one in the cartilage of the meatus. The fissure of the helix is a short vertical slit, situated at the forepart of the pinna. Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. Anteriorly and inferiorly the cartilage of the pinna is continuous with the cartilage of the external auditory meatus by a cartilaginous isthmus (isthmus cartilaginis auris). Some authors regard the tragus as part of the cartilage of the meatus. The cartilage of the pinna is very pliable, elastic, of a yellowish color and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

**The Ligaments of the Pinna (ligamenti auricularia [Valsalvae]).**—The ligaments of the pinna consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The Extrinsic Ligaments, the most important, are three in number: superior, anterior, and posterior. The superior ligament (ligamentum auriculare superius) extends from the suprameatal spine to the spine of the helix. The anterior ligament (ligamentum auriculare anterius) extends from the spina helicis and tragus to the
root of the zygoma. The posterior ligament (ligamentum auriculare posterius) passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The chief Intrinsic Ligaments are: (1) a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (2) a band which extends between the antihelix and the cauda helicis. Other less important bands are found on the cranial surface of the pinna.

The Muscles of the Pinna (Figs. 753 and 755).—The muscles of the pinna consist of two sets: 1. The extrinsic, which connect it with the side of the head, moving the pinna as a whole—viz., the Attollens, Attraheis, and Retraheis auriculam (p. 369). 2. The intrinsic, which extend from one part of the auricle to another, viz.:

| Helicis major. | Antitragicus. |
| Helicis minor. | Transversus auriculae. |
| Tragicus.     | Obliquus auriculae. |

The Helicis Major (m. helicis major) is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises, below, from the cauda helicis, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

The Helicis Minor (m. helicis minor) is an oblique fasciculus which covers the crus helicis.

The Tragicus (m. tragicus) is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The Antitragicus (m. antitragicus) arises from the outer part of the antitragus; its fibres are inserted into the cauda helicis and antihelix. This muscle is usually very distinct.

The Transversus Auriculae (m. transversus auriculae) is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The Obliquus Auriculae (Tod) (m. obliquus auriculae) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The Arteries of the Pinna.—The arteries of the pinna are the posterior auricular from the external carotid, the anterior auricular from the temporal and an auricular branch from the occipital artery.

The Veins of the Pinna.—The veins of the pinna accompany the corresponding arteries.

The Lymphatics of the Pinna.—The lymphatics enter into the pre-auricular glands and the glands upon the Sterno-mastoid muscle at its insertion.
The Nerves of the Pinna.—The nerves of the pinna are: the auricularis magnus, from the cervical plexus; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus, and the occipitalis major or internal branch of the posterior division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The External Auditory or External Acoustic Canal or External Auditory Meatus (Meatus Acusticus Externus or Meatus Auditorius Externus).

The external auditory or acoustic canal or meatus extends from the bottom of the concha to the membrana tympani (Figs. 752, 756, and 757). It is about an inch and a half in length if measured from the tragus; from the bottom of the concha its length is about an inch. It forms a sort of S-shaped curve, and is directed at first inward, forward, and slightly upward (pars externa); it then passes inward and backward (pars media), and lastly is carried inward, forward, and slightly downward (pars interna). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the isthmus, in the osseous portion, about three-quarters of an inch from the bottom of the concha. The membrana tympani (Figs. 756 and 757), which occupies the termination of the meatus, is directed obliquely, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, partly by bone, and is lined by perichondrium and periosteum, which is covered with skin.

The Cartilaginous Portion (meatus acusticus externus cartilagineus).—The cartilaginous portion is about one-third of an inch (8 mm.) in length; it is formed by the cartilage of the pinna, prolonged inward, and firmly attached to a greater portion of the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures, the fissures of Santorini (incisurae cartilagineae meatus acustici externi [Santorini]), which extend through the cartilage in a vertical direction. It is firmly attached at its lower and front part to the posterior root of the zygoma and to the lateral edge of the tympanic portion of the temporal bone.
The Osseous Portion (meatus acusticus externus osseus).—The osseous portion is about two-thirds of an inch (16 mm.) in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove, the tympanic sulcus (sulcus tympanicus), for the insertion of the membra tympani. Its outer edge is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate of bone, which, in the fetus, exists as a separate ring (annulus tympanicus), incomplete at its upper part. (See Section on Osteology.)

The Skin of the Meatus.—The skin lining the meatus is a prolongation of the external skin; it is thin, adheres closely to the cartilaginous and osseous portions of the tube, and covers the surface of the membrana tympani, forming a very thin outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands (glandulae ceruminosae) which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

Relations of the Meatus.—In front of the osseous part is the glenoid fossa, which receives the condyle of the mandible (Fig. 759), which, however, is separated from the cartilaginous part by the retromandibular part of the parotid gland. The movements of the jaw influence to some extent the lumen of the cartilaginous portion. Behind the osseous part are the mastoid air-cells, separated from it by a thin layer of bone (Fig. 46).

The Arteries of the External Meatus.—The arteries supplying the external meatus are branches from the posterior auricular, internal maxillary, and superficial temporal.
The Veins of the External Meatus.—Veins accompany the corresponding arteries and pass to the internal maxillary, temporal, and posterior auricular veins.

The Lymphatics of the External Meatus.—The lymphatics accompany the veins and enter the parotid and posterior auricular lymph-glands.

The Nerves of the External Meatus.—The nerves are derived from the auriculo-temporal branch of the inferior maxillary nerve, the auriculotemporal, and the auriculotemporal branch of the pneumogastric.

Surface Form.—The point of junction of the osseous and cartilaginous portions of the tube is an obtuse angle, which projects into the canal at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ear. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is short, the osseous part being very deficient, and consisting merely of a bony ring (annulus tympanicus), which supports the membrana tympani. In the fetus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it shall not be pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about 55 degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal—being situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane (Fig. 760). At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

THE MIDDLE EAR, DRUM OR TYMPANUM (AURIS MEDIA) (Figs. 756, 757, 758, 762).

The middle ear or tympanum is an irregular cavity, compressed from without inward, and is situated within the petrous portion of the temporal bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the external auditory meatus externally, and the labyrinth internally. It is lined with mucous membrane, is filled with air, and communicates with the mastoid cells, and with the naso-pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the external ear. In shape it is roughly biconcave, the concave surfaces being placed vertically and forming the external and internal walls. The cavity forms an angle of 45 degrees with the median plane (Spalteholz).

The Tympanic Cavity (cavum tympani) (Figs. 762 and 763).—The tympanic cavity consists of two parts: the atrium or tympanic cavity proper (Fig. 763), opposite the tympanic membrane, and the attic or epitympanic recess or aditus ad antrum (recessus epitympanicus) (Figs. 761 and 762), above the level of the
upper part of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. The diameter of the tympanic cavity, including the attic, measures about $\frac{3}{8}$ inch (15 mm.) vertically and transversely. From without inward it measures about $\frac{1}{4}$ inch (6 mm.) above and $\frac{1}{8}$ inch (4 mm.) below; opposite the centre of the tympanic membrane it is only about $\frac{1}{16}$ inch (2 mm.). It is bounded externally by the membrana tympani and meatus; internally, by the outer surface of the internal ear; and communicates behind with the mastoid antrum and through it with the mastoid cells; and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminae, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The Roof of the Tympanum (paries tegmentalis).—The roof of the tympanum is broad, flattened, and formed of a thin plate of bone (tegmen tympani) (Fig. 762), which separates the cranial and tympanic cavities. It is prolonged backward so as to roof in the mastoid antrum; it is also carried forward to cover in the canal for the Tensor tympani muscle.

The Floor (paries jugularis) (Fig. 762).—The floor is narrow, and is separated by a thin plate of bone (fundus tympani) from the jugular fossa. It frequently presents numerous small notches in the bone (cellulae tympanicae). There is one small aperture in the floor. It is near the inner wall and is the opening of the canaliculus tympanicus, for the transmission of Jacobson’s nerve (n. tympanicus). On the floor near the posterior wall there is often to be found a slight bony projection (prominentia styloidea).

The Outer Wall (Fig. 757).—The outer wall is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. The part formed by the membrana tympanum is called the paries membranaceus. This ring of bone is incomplete at its upper part, forming a notch, the notch of Rivinus (incisura tympanica [Rivini]) (Fig. 760). The anterior edge of the notch is known as the spina tympanica major, the posterior edge as the spina tympanica minor. The groove for the reception of the membrana tympani is the sulcus tympanicus. Close to the notch are three small apertures: the iter chordae posteriori, the Glaserian fissure, and the iter chordae anterius.

The iter chordae posteriori or the tympanic aperture (canaliculus chordae tympani) (Fig. 761) is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends

Fig. 758.—View of the inner wall of the tympanum (enlarged).
in front of the aquaeductus Fallopii, and terminates in the aqueduct near the stylomastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The Glaserian or petro-tympanic fissure (fissura petrotympanica [Glaseri]) (Fig. 761) opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The iter chordae anterius (Fig. 761) is seen at the inner end of the preceding fissure; it leads into a canal, the canal of Huguier, which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The outer wall bounds the epitympanic recess externally.

The Internal Wall of the Tympanum ( partes labyrinthica) (Figs. 758 and 762).—The internal wall of the tympanum is adjacent to the labyrinth, is vertical in direction, and looks directly outward. It presents for examination the following parts:

- Fenestra ovalis. Promontory.
- Fenestra rotunda. Ridge of the aquaeductus Fallopii.
- Prominence of the external semicircular canal.

The Fenestra Ovalis, the Oval or the Vestibular Window ( fenestra vestibuli) (Fig. 758) is a reniform opening leading from the tympanum into the vestibule. It is situated in the depths of a fossa (fossula fenestrae vestibuli). Its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes (Figs. 757 and 763), which is connected to the margin of the foramen by an annular ligament.

The Fenestra Rotunda, the Round or Cochlear Window ( fenestra cochleae) (Fig. 758) is an aperture placed at the bottom of a funnel-shaped depression (fossula fenestrae cochleae) leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the promontory; at its border is a narrow ridge of bone (crista fenestrae cochleae), and it is closed in the recent state by a membrane, the membrane of Scarpa or the secondary ear-drum membrane (membrana tympani secundaria). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external or mucous, derived from the mucous lining of the tympanum; the internal, from the lining membrane of the cochlea; and an intermediate or fibrous layer.

The Promontory ( promontorium) (Fig. 762) is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestrae, and is furrowed on its surface (sulcus promontorii) for the lodgement of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramid.

The Rounded Eminence of the Aquaeductus Fallopii ( prominencia canalis facialis) (Fig. 762), the prominence of the bony canal in which the facial nerve is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

Just above the eminence of the aquaeductus Fallopii the wall is bulged by the external semicircular canal ( prominencia canalis semicircularis lateralis).

The Posterior Wall of the Tympanum ( paries mastoidea) (Fig. 762).—The posterior wall of the tympanum is wider above than below, and the lower portion of the posterior wall contains many tympanic cells: The posterior wall presents for examination the—

- Opening of the antrum. Prominentia styloideae.
- Fossa incudis. Pyramid.
- Apertura tympanica canaliculi chordae.
The Opening of the Antrum is a large irregular aperture, which extends backward from the epitympanic recess and leads into a considerable air space, the mastoid antrum (antrum tympanicum), which is the entrance to the mastoid cells (p. 87). The antrum communicates with large irregular cavities contained in the interior of the mastoid process, the mastoid air-cells. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The Fossa Incudis (Fig. 762) is placed in the posterior and inferior part of the epitympanic recess. It lodges the short process of the incus.

The Prominentia Styloidea is sometimes seen below the apertura tympanica canaliculi chordae. It is a prominence produced by a prolongation of the styloid process.

The Pyramid (eminentia pyramidalis) (Fig. 758) is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aqueductus Fallopii and transmits the nerve which supplies the Stapedius.

The Apertura Tympanica Canaliculi Chordae is just back of the posterior edge of the tympanic membrane, nearly level with the superior end of the manubrium mallei.

The Anterior Wall of the Tympanum (paries caroticus).—The anterior wall of the tympanum is bony on its lower portion. Its upper part is the tympanic opening of the Eustachian tube. The long anterior wall contains tympanic cells. The anterior wall is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone (Fig. 762), perforated by the canaliculi caroticotympanic, which transmit the tympanic branch of the internal carotid artery and the carotico-tympanic nerves. It presents for examination the—

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being incompletely separated from each other by a thin, delicate, horizontal plate of bone, the processus cochleariformis (septum canalis musculotubarii) (Figs. 49 and 758). The canalis musculotubarius is divided by this long process into the canal for the Tensor tympani and the canal for the Eustachian tube. These canals run from the tympanum forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The Canal for the Tensor Tympani (semicanalis m. tensoris tympani) (Figs. 49, 758, and 762) is the superior and the smaller of the two; it is rounded and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the fenestra ovalis. The processus cochleariformis passes backward below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the fenestra ovalis and terminates by curving outward so as to form a pulley over which the tendon passes. The bony wall of this canal is incomplete, and the osseous vacancy is filled by tough connective tissue.

The Eustachian Tube or Ear Trumpet (tuba auditiva [Eustachii]) (Figs. 49, 758, and 759) is the channel through which the tympanum communicates with the pharynx. Its length is an inch and a half (36 mm.), and its direction downward, inward, and forward, forming an angle of about 45 degrees with the sagittal plane and one of from 30 to 40 degrees with the horizontal plane.
The canal for the Eustachian tube (semicanalis tubae auditivae) (Fig. 759) is formed partly of bone, partly of cartilage and fibrous tissue.

The Osseous Portion (pars ossea tubae auditivae or semicanalis tubae auditivae) is about half an inch in length. It is the outer portion of the tube. It commences in the anterior wall of the tympanum, below the processus cochleariformis (ostium tympanicum tubae auditivae), and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion. The roof of the osseous portion is the tegmen tympani. The inner wall is formed in part by the inner wall of the tympanum and in part by the canal for the Tensor tympani muscle. The outer wall is the tympanic portion of the temporal bone. The floor is a groove which near the tympanum contains the openings of air-cells (cellulae pneumatici tubarit).

![Diagram of Eustachian tube]

The Cartilaginous Portion (pars cartilaginea tubae auditivae), about an inch in length, is formed of a triangular plate of elastic fibro-cartilage (cartilago tubae auditivae), the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the naso-pharynx, where it forms an elevation or cushion above and behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outward so as to present on transverse section the appearance of a hook (lamina lateralis); a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. On transverse section the cartilage exhibits the laminae which above are continuous with each other: the hard, thick lamina medialis and the thin and hooked lamina lateralis. The cartilage of the Eustachian tube, with a hood plate of cartilage, forms the posterior portion of the inner wall (the lamina medialis). The cartilage is fixed to the base of the skull, and lies in a groove (sulcus tubae auditivae) between the petrous-temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate, in a projection, the
processus tubarius. At the pharyngeal orifice the entire wall of the tube is cartilaginous, but the breadth of the cartilage progressively lessens as the isthmus is approached. Here and there the cartilage is deficient or pieces lie separate from the rest, the spaces between the islands being occupied by fibrous tissue. The Tensor palati muscle is placed to the outer side of the tube. The fibres of the muscle which take origin from the lamina lateralis are known as the dilator tubae muscle of Rudinger. The Tensor palati muscle and the mucous membrane of the pharynx lie to the inner side of the tube. The under and outer portion of the canal is completed by the membranous part (lamina membranacea), which is a strong fibrous membrane, passing between the two margins of the cartilage. It is thin above, but thick below, and the thick portion is called the fascia salpingopharyngea of Tröltzsch, and from it arise some fibres of the Tensor palati (m. salpingopharyngeus). The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downward a little more than the latter. They join each other at a large obtuse angle, open below. The diameter of the canal is not uniform throughout, being greatest at the pharyngeal orifice and least at the junction of the bony and cartilaginous portions, where it is named the isthmus (isthmus tubae auditivae); it again expands somewhat as it approaches the tympanic cavity. The position and relations of the pharyngeal orifice (ostium pharyngeum tubae auditivae) are described with the anatomy of the naso-pharynx. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the tube-tonsil. The tube is opened during deglutition by the Salpingo-pharyngeus and Dilator tubae muscles.

The Drumhead or Membrana Tympani (Figs. 757, 759, 760, and 761).—The membrana tympani or drumhead separates the cavity of the tympanum from

![Diagram](image-url)
the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward, so as to form an angle of about 55 degrees with the floor of the meatus (Fig. 757). The antero-inferior portion is, therefore, placed at the greatest distance from the external orifice of the meatus. It is asserted that in musicians the membrana tympani is placed more nearly perpendicular, and that in deaf-mutes and cretins it is placed more obliquely than the usual 55 degrees. In a newborn child the membrana tympani is almost horizontal. The greatest diameter of the membrana tympani is from 9 to 10 mm.; its least diameter is from 8 to 9 mm. The greater part of its circumference (limbus membranae tympanae) is thickened to form an annular ring (annulus fibrocartilagineus), which is fixed in a groove, the sulcus tympanicus, at the inner extremity of the external meatus. This sulcus is deficient superiorly at the incisure or notch of Rivinus (inceisura tympanica [Rivini]) (Fig. 760). From the extremities of the notch (spinae tympanicae) two folds pass and converge to the short process of the malleus (Fig. 760). One is known as the anterior tympanomalleolar fold or ligament (plica membrana tympani anterior). The other is known as the posterior tympanomalleolar fold or ligament (plica membrana tympani posterior). These are not to be confused with the anterior and posterior malleolar folds (p. 1162). The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the flaccid portion or the membrana flaccida of Shrapnell (Figs. 760 and 761). In it a small orifice is sometimes seen, which is of artificial and pathological formation. The larger lower portion of the drum membrane is stretched tightly, and is called the tense portion or pars tensa (Figs. 760 and 761).

1 Prof. Cunningham's Text-book of Anatomy.
The handle of the malleus is firmly attached to the inner aspect of the membrana tympani as far as its centre (Fig. 761). It draws the central part of the membrane inward and makes its outer aspect concave. The most depressed part of the concavity is called the umbo or navel (umbo membranae tympanae) (Fig. 760). The walls of the umbo are convex outward.

On the outer surface of the drum membrane a light stripe (stria malleolaris) is seen. It runs from in front and above downward and backward, and is produced by the handle of the malleus, showing through the membrane (Fig. 760).

Structure.—This membrane is composed of three layers: an external (cuticular), a middle (fibrous), and an internal (mucous). The cuticular lining (stratum cutaneum) is derived from the integument lining the meatus. The fibrous or middle layer (membrana propria) consists of two strata: an external, of radiating fibres (stratum radiatum), which diverge from the handle of the malleus, and an internal, of circular fibres (stratum circulare), which are plentiful around the circumference, but sparse and scattered near the centre of the membrane. Branched or dendritic fibres, as pointed out by Grüber, are also present, especially in the posterior half of the membrane. Both muscular layers are connected to the annulus fibrocartilagineus, and both are absent in the pars flaccida. The inner or epithelial layer is mucous membrane (stratum mucosum), which is a portion of the mucous membrane of the drum cavity.

The Arteries are derived from the deep auricular branch of the internal maxillary, which ramifies beneath the cuticular layer and from the stylo-mastoid branch of the posterior auricular and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The arteries of the cutaneous set anastomose with the arteries of the mucous set by minute branches which penetrate the drum membrane near its margin. The superficial veins open into the external jugular; those on the mucous surface drain themselves partly into the lateral sinus and veins of the dura mater and partly into a plexus on the Eustachian tube.
The outer surface of the drum membrane receives its nervous supply from the auriculo-temporal branch of the inferior maxillary and the auricular branch of the vagus. The inner surface is supplied by the tympanic branch of the glossopharyngeal.

There are two sets of lymphatics, the cutaneous and mucous, which freely communicate. The spaces between the dendritic fibres of Grüber are lymph-spaces (Kessel).

**The Ossicles of the Tympanum (Ossicula Auditus) (Fig. 763).**

The tympanum contains in its upper part a chain of movable bones, three in number, the **malleus, incus, and stapes.** The first is attached to the membrana tympani, the last to the fenestra ovalis. The incus is placed between the two, and is connected to both by delicate articulations.

**The Malleus or Hammer (Fig. 764).**—The malleus or hammer, so named from its fancied resemblance to a hammer, is placed farthest in front and outward. It consists of a head, neck, and three processes—the **handle or manubrium,** the **processus gracilis,** and the **processus brevis.**

**The Neck (collum mallei).**—The neck is the large upper extremity of the bone, and is situated in the epitympanic recess (Fig. 761). It is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is covered with cartilage, is constricted near the middle, and is divided by a ridge into an upper, larger, and a lower, lesser part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the **cog-tooth or spur of the malleus.** On the back of the head below the spur is a crest (**crista mallei**), to which the posterior ligament of the malleus is attached.

**The Neck (collum mallei).**—The neck is the narrow contracted part just beneath the head; and below this is a prominence, to which the various processes are attached. The outer surface of the neck faces the membrana flaccida. The chorda tympani nerve crosses the inner surface (Fig. 761).

**The Handle or Manubrium (manubrium mallei).**—The manubrium is a vertical process of bone, which is connected by its outer margin with the fibrous layer of the membrana tympani, its entire length being fastened to the fibrous layer of the drum membrane by its own periosteum and by a layer of cartilage (Grüber) (Figs. 761 and 763). It is directed downward, inward, and backward; it decreases in size toward its extremity, where it is curved slightly forward, and is flattened from within outward. The handle forms a variable angle with the head of the hammer. It averages about 130 degrees, but is always greater in the right ear than in the left. It forms an angle with the horizontal, averaging on the right side 50 degrees and on the left side 45 degrees (Spalteholz). Internally the handle is covered by the mucous membrane of the tympanum. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted (Fig. 761).

**The Processus Gracilis or Long Process (processus anterior [Foli]).**—The processus gracilis is a long and very delicate process, which passes from the front of
the neck forward and outward to the Glaserian fissure, to which it is connected by ligamentous fibres. In the fetus this is the longest process of the malleus, and is in direct continuity with the cartilage of Meckel.

The Processus Brevis (processus lateralis).—The processus brevis is a slight conical projection, which springs from the root of the manubrium; it is directed outward, and is attached to the upper part of the tympanic membrane by cartilage and to the margins of the notch of Rivinus by the two malleolar folds.

The Incus or Anvil (Fig. 765).—The incus or anvil has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth with two roots, which differ in length, and are widely separated from each other. It consists of a body and two processes. The body and the short process are placed in the epitympanic recess (Fig. 763).

The Body (corpus incudis).—The body is somewhat quadrilateral, but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus, and the lower part is hollowed for the spur of the malleus. In the fresh state the articular surface is covered with cartilage and the joint is lined with synovial membrane.

Processes.—The two processes diverge from one another at an angle of from 90 to 100 degrees.

The Short Process (crus breve), somewhat conical in shape, projects nearly horizontally backward, and articulates with a depression, the incus fossa (fossa incudis), in the lower and back part of the epitympanic recess.

The Long Process (crus longum), longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and,
bending inward, terminates in a rounded globular projection, the os orbiculare or lenticular process (processus lenticularis), which is tipped with cartilage, and articulates with the head of the stapes. In the foetus the os orbiculare exists as a separate bone.

The Stapes or Stirrup (Fig. 766).—The stapes or stirrup, so called from its close resemblance to a stirrup, consists of a head, neck, two crura, and a base.

The Head (capitulum stapedis).—The head presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The Neck.—The neck, the constricted part of the bone preceding the head, receives the insertion of the Stapedius muscle.

The Crura.—The two crura (crus anterius and crus posterius) diverge from the neck and are connected at their extremities by a flattened, oval-shaped plate, the foot-plate or base (basis stapedis), which forms the foot-plate of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres. The foot-plate almost fills the oval window (Fig. 757). Of the two crura, the anterior is shorter and less curved than the posterior. In a recent specimen a membrane will be observed filling the space between the crura and the foot-plate. This membrane is connective tissue and is called the membrana obturatoria stapedis. The stirrup lies practically horizontal.

Articulations of the Ossicles of the Tympanum (articulationes ossiculorum auditus) (Fig. 763).—These small bones are connected with each other and with the walls of the tympanum by ligaments, and are moved by small muscles. There is an articulation between the head of the hammer and the body of the anvil; one between the os orbiculare of the anvil and the head of the stirrup; and there is a syndesmosis between the margins of the oval window and the base of the stirrup.

The bones are fastened in the tympanum, the handle of the hammer being fastened in the drum membrane and the base of the stirrup to the oval window. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane.

Ligaments Connecting the Ossicula with the Walls of the Tympanum (ligamenta ossiculorum auditus).—The malleus is fastened to the wall of the tympanum by three ligaments: the anterior, superior, and external ligaments.

The Anterior Ligament of the Malleus (ligamentum mallei anterius) consists of two parts, the band of Meckel and the anterior ligament of Helmholtz.

The band of Meckel is attached to the base of the processus gracilis and passes through the Glaserian fissure to reach the spine of the sphenoid. It was formerly described by Sömmering as a muscle, and it was called the laxator tympani muscle. It is now, however, believed by most observers to consist of ligamentous fibres only.

The anterior ligament of Helmholtz extends from the anterior margin of the notch of Rivinus to the anterior portion of the malleus, just above the processus gracilis.

The Superior Ligament of the Malleus (ligamentum mallei superius) is a delicate round bundle of fibres which descends perpendicularly from the roof of the epi-tympanic recess to the head of the malleus. It is sometimes called the suspensory ligament.

The External Ligament of the Malleus (ligamentum mallei laterale) is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring.
(incisura Rivini) to the crest of the malleus. The posterior portion of the external ligament is sometimes called the posterior ligament of Helmholtz (ligamentum mallei posterius [Helmholtzi]). The malleus rotates around an axis composed of the external and anterior ligaments, hence these two ligaments constitute what Helmholtz called the axis ligament of the malleus.

The incus is fastened to the wall of the tympanum by two ligaments, the posterior and the superior.

The Posterior Ligament of the Incus (ligamentum incudis posterius) is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior and lower part of the epitympanic recess, near the margin of the opening of the mastoid cells.

A Superior Ligament of the Incus (ligamentum incudis superiorius) has been described by Arnold, but it is little more than a fold of mucous membrane.

The inner surface and the circumference of the base of the stapes are covered with hyaline cartilage, and the annular ligament of the stapes (ligamentum annulare baseos stapedis) connects the circumference of the base to the margin of the fenestra ovalis.

The Muscles of the Tympanum (m. ossiculorum auditus).—The muscles of the tympanum are two:

Tensor tympani. Stapedius.

The Tensor Tympani (m. tensor tympani) (Fig. 762), the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward around the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. Its nerve-supply is from the motor root of the fifth cranial nerve by way of the otic ganglion.

The Stapedius (m. stapedius) (Fig. 762) arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The Tensor tympani draws the handle of the malleus inward and thus heightens the tension of the drum membrane. It also causes slight rotation of the bone around its long axis. When the Stapedius contracts it draws the head of the stirrup backward, and in consequence the anterior end of the footplate passes outward toward the tympanum, and the posterior end inward toward the vestibule, and the annular ligament is made tense.

Movements of the Ossicles of the Tympanum.—The chain of bones is a lever-like arrangement, by means of which the vibrations of the membrana tympani are transferred to the membrane covering the oval window, and from this to the peri-lymph in the labyrinth. When the drum membrane moves inward, the handle of the malleus moves with it. The movement of the malleus moves the incus, and the movement of the incus drives the foot of the stapes toward the labyrinth. When the handle of the malleus moves inward, the spur on the head becomes locked with the body of the incus. During outward movement it is unlocked. The ordinary outward movement of the drum membrane causes the above-described movements to be reversed. When there is overforcible outward movement the incus does not go outward quite as far as the malleus, but slides at the joint between the malleus and incus. This reluctance of the incus saves the foot of the stapes from being pulled away from the oval window.
The Mucous Membrane of the Tympanum (tunica mucosa tympanica).—The mucous membrane of the tympanum is continuous with the mucous membrane of the naso-pharynx through the Eustachian tube, and is firmly united to the periosteum. It invests the ossicles, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani, and the outer layer of the membrana tympani secundaria, and is reflected into the mastoid antrum and air-cells, which it lines throughout. It forms several vascular folds (plicae), which extend from the walls of the tympanum to the ossicles. In these folds the ossicles are enveloped.

The anterior malleolar fold (plica malleolaris anterior) comes off from the membrana tympani between the anterior edge of the notch of Rivinis and the handle of the malleus, envelops the processus gracilis of the malleus, the anterior ligament of the malleus, and the anterior portion of the chorda tympani nerve, and terminates in a free concave edge (Spalteholz). The posterior malleolar fold (plica malleolaris posterior) is the larger of the two. It comes off from the margin of the notch of Rivinis, envelops the external ligament of the malleus, the posterior part of the chorda tympani nerve, is attached to the handle of the malleus, and ends in a free concave margin (Spalteholz). The fold of the incus (plica incudis) takes origin from the roof of the epitympanic recess and passes to the body and short process of the incus; and a similar fold passes from the head of the malleus to the anterior wall of the epitympanic recess. The entire stapes, with its obturator membrane, is enwrapped by the fold of the stapes (plica stapedis). This fold also ensheaths the tendon of the stapedius muscle and often reaches to the posterior wall of the cavity of the tympanum. The mucous membrane over the round window forms the membrana tympani secundaria. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honey-comb appearance. One of these pouches is well marked—viz., the pouch of Prussak, which lies between the neck of the malleus and the membrana flaccida.

The inferior external pouch of the tympanum or the pouch of Prussak (recessus membranae tympani superior) is between the flaccid portion of the membrana tympani, the external ligament of the malleus, and the neck of the malleus. The anterior and posterior malleolar folds with the tympanic membrane form two pouches. These are the anterior and posterior pouches or recesses of Trötsch (recessus membranae tympani, anterior and posterior). The anterior pouch is blind above and has a slit-like opening below. The posterior pouch is continued into the blind superior pouch of the drum membrane. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that covering the pyramid, ossicula, and membrana tympani possesses a flattened, non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin; but in the cartilaginous portion it is very thick, highly vascular, covered with ciliated epithelium, and provided with numerous mucous glands.

The Arteries of the Tympanum.—The arteries supplying the tympanum are six in number. Two of them are larger than the rest—viz., the tympanic branch of the internal maxillary, which enters by way of the Glaserian fissure and supplies the membrana tympani; and the stylo-mastoid branch of the posterior auricular, which passes through the stylo-mastoid foramen and the aqueduct of Fallopius, and supplies the inner wall and floor of the tympanum, the mastoid cells, and antrum and the Stapedius muscle. This vessel anastomoses around the drum membrane with the tympanic. The middle meningeal sends a small branch to the Tensor tympani muscle near its origin. The petrosal branch of the middle meningeal enters the tympanum by way of the hiatus Fallopii. Minute branches from the posterior branch of the middle meningeal pass through the petro-
squamous fissure and are distributed to the antrum and epitympanic recess (Cunningham). Two tympanic branches come off from the internal carotid artery in its course through the carotid canal. A branch from the ascending pharyngeal and another from the Vidian, accompany the Eustachian tube. The two tympanic branches from the internal carotid are given off in the carotid canal and perforate the thin anterior wall of the tympanum.

The Veins of the Tympanum.—The veins of the tympanum terminate in the pterygoid plexus, the middle meningeal vein, and the superior petrosal sinus.

The Nerves of the Tympanum.—The nerves of the tympanum constitute the tympanic plexus (plexus tympanicus [Jacobsoni]), which ramifies upon the surface of the promontory (Fig. 762). The plexus is formed by (1) the tympanic branch of the glossopharyngeal; (2) the small deep petrosal nerve; (3) the superficial petrosal nerve; and (4) a branch which joins the great superficial petrosal.

The Tympanic Branch of the Glossopharyngeal or Jacobson's Nerve (n. tympanicus) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The small deep petrosal nerve (n. petrosus profundus), from the carotid plexus of the sympathetic, passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. The small superficial petrosal nerve (n. petrosus superficialis minor), derived from the otic ganglion, passes through a foramen in the middle fossa of the base of the skull (sometimes through the foramen ovale), passes backward and enters the petrous bone through a small aperture, situated external to the hiatus Fallopii on the anterior surface of this bone; it then courses downward through the bone, and, passing by the gangliform enlargement of the facial nerve, receives a connecting filament from it (Fig. 670) and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The branches of distribution of the tympanic plexus are distributed to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as a branch from the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the fifth through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The chorda tympani (Figs. 758 and 761) crosses the tympanic cavity. It is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, iter chordae posterius, already described (p. 1151), and becomes invested with mucous membrane. It passes forward, through the cavity of the tympanum, crossing internal to the membrana tympani and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through the iter chordae anterius or canal of Huguier (p. 1152). It is invested by the fold of mucous membrane already mentioned, and therefore lies between the mucous and fibrous layers of the membrana tympani.

THE INTERNAL EAR OR LABYRINTH (AURIS INTERNA).

The internal ear is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the labyrinth, from the
complexity of its shape, and consists of two parts: the osseous labyrinth, a series of cavities channelled out of the substance of the petrous bone, and the membranous labyrinth, the latter being contained within the former.

The Osseous Labyrinth (Labyrinthus Osseus) (Fig. 767).

The osseous labyrinth consists of three parts: the vestibule, semicircular canals, and cochlea. These are cavities hollowed out of the substance of the bone, and lined by periosteum. A clear fluid is contained in the space between the osseous labyrinth and the membranous labyrinth. The space is called the perilymph space, and the fluid is called perilymph or liquor Coturnii.

The Vestibule (vestibulum) (Figs. 763 and 767).—The vestibule is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before back-

Fig. 767.—The osseous labyrinth laid open (enlarged).

ward, as well as from above downward, and about one-eighth of an inch from without inward. On its outer or tympanic wall is the fenestra ovalis (fenestra vestibuli), closed, in the recent state, by the base of the stapes, and its annular ligament. On its inner wall, at the forepart, is a small circular depression, fovea hemisphaerica or spherical recess (recessus sphaericus), in which the saccule is placed. This recess is perforated, at its anterior and inferior part, by about a dozen minute holes (macula cribrosa media), for the passage of filaments of the auditory nerve to the saccule. Above and behind this depression is an oblique ridge, the crista vestibuli. The anterior extremity of the crista vestibuli is the shape of a triangle, and is called the pyramid (pyramis vestibuli). This ridge bifurcates posteriorly to enclose a small depression, the recessus cochlearis of Reichert, which is perforated by eight small holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. An oval depression is placed in the roof and inner wall of the vestibule above and behind the crista vestibuli. It is called the fovea hemielliptica, elliptical recess or spherical recess (recessus ellipticus), and receives the utricle. The pyramid and the adjacent elliptical recess are perforated by numerous minute foramina (macula cribrosa superior),
The openings in the pyramid transmit filaments from the vestibular nerve to the utricle; the openings in the elliptical recess transmit filaments from the vestibular nerve to the ampullae of the superior and external semicircular canals. Below and behind the elliptical recess is a groove which deepens into a canal and is called the aquaeductus vestibuli. This canal passes to the posterior surface of the petrous portion of the temporal bone and opens as a mere crack between the internal auditory meatus and the groove for the lateral sinus. It transmits a small vein, and contains a tubular prolongation of the lining membrane of the vestibule, the ductus endolymphaticus, which ends in a cul-de-sac between the layers of the dura mater within the cranial cavity. Behind, the semicircular canals open into the vestibule by five orifices. In front is an elliptical opening, which communicates with the scala vestibuli of the cochlea by an orifice, apertura scalae vestibuli cochleae. This opening is bounded below by a thin plate of bone (lamina spiralis ossea), which takes origin from the vestibular floor external to the spherical recess and in the cochlea forms the bony portion of the partition between the scala tympani and the scala vestibuli. In the anterior portion of the vestibular floor is a fissure (fissura vestibuli), which passes into the bony part of the canal of the cochlea. The external boundary of this fissure is a small, thin plate of bone (lamina spiralis secundaria).

The Semicircular Canals (canales semicirculares ossei) (Fig. 767).—The semicircular canals are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and each describes the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the ampulla ossea, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals. The Superior Semicircular Canal (canalis semicircularis superior).—The superior semicircular canal is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, communicates by a distinct orifice with the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal to form the crus commune, which opens into the upper and inner part of the vestibule.

The Posterior Semicircular Canal (canalis semicircularis posterior).—The posterior semicircular canal, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three; its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned. In the wall of the ampulla of the posterior canal are a number of small openings (macula cribrosa inferior) for the entrance of nerves to the ampulla.

The External or Horizontal Canal (canalis semicircularis lateralis).—The external or horizontal canal is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The Cochlea (Figs. 767, 768, 769, and 770).—The cochlea bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward, with a slight inclination downward, toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous
apertures for the passage of the cochlear divisions of the auditory nerve. It measures nearly a quarter of an inch (5 mm.) from base to apex, and its breadth across the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the modiolus or columella; of a canal, the bony canal of the cochlea, the inner wall of which is formed by the central axis, wound spirally around it for two turns and three-quarters, from the base to the apex, and of a delicate lamina, the lamina spiralis ossea, which projects from the modiolus, and, following the windings
of the canal, partially subdivides into two. In the recent state certain mem-
branous layers are attached to the free border of this lamina, which project into
the canal and completely separate it into two passages, which, however, com-

municate with each other at the apex of the modiolus by a small opening, named
the helicotrema.

The Modiolus (Figs. 769 and 770).—The modiolus or columnella is the central axis
or pillar of the cochlea. It is conical in form, and extends from the base to the apex
of the cochlea. Its base (basis modioli) is broad, and appears at the bottom of the
internal auditory meatus, where it corresponds with the area cochleae. It is per-
formed by numerous orifices, which transmit filaments of the cochlear division
of the auditory nerve, the nerves for the first turn and a half being transmitted
through the foramina of the tractus spiralis foraminosus; the fibres for the apical
turn passing up through the foramen centrale. The foramina of the tractus
spiralis foraminosus pass up through the modiolus and successively bend out-
ward to reach the attached margin of the lamina spiralis ossea. Here they become
enlarged, and by their apposition form a spiral canal (canalis spiralis modioli),
which follows the course of the attached margin of the lamina spiralis ossea and
lodges the ganglion of Corti (ganglion spirale cochleae). The foramen centrale is
continued as a canal up the middle of the modiolus to its apex, and from this canal
numerous minute foramina pass outward to the unattached edge of the lamina
spiralis. In the foramina are vessels and nerves. The axis diminishes rapidly
in size in the second and succeeding coil.

The Bony Canal or the Spiral Canal of the Cochlea (canalis spiralis cochleae) (Fig.
770).—The bony canal of the cochlea takes two turns and three-quarters round the
modiolus. The first turn of the canal is called the basal coil, the second is called the
central coil, the third turn is called the apical coil. The promontory on the inner wall
of the tympanic cavity is caused by the basal coil. The bony canal of the cochlea is
a little over an inch in length (about 30 mm.), and diminishes gradually in size from
the base to the summit, where it terminates in a cul-de-sac, the cupola (cupula), which
forms the apex of the cochlea. The commencement of this canal is about the
tenth of an inch in diameter; it diverges from the modiolus toward the tympanum
and vestibule, and presents three openings. One, the fenestra rotunda, commu-
nicates with the tympanum; in the recent state this aperture is closed by a mem-
brane, the membrana tympani secundaria. Another aperture, of an elliptical form,
enters the vestibule. The third is the aperture of the aquaeductus cochleae, leading
to a minute funnel-shaped canal, which opens on the basilar surface of the petrous
bone internal to the jugular fossa, and transmits a small vein, and also forms a
communication between the subarachnoideal space of the skull and the peri-
lymph contained in the scala tympani.

The Lamina Spiralis Ossea.—The lamina spiralis ossea is a bony shelf or ledge
which projects outward from the modiolus into the interior of the spiral canal,
and, like the canal, takes two and three-quarter turns around the modiolus. It reaches about half-way toward the outer wall of the spiral tube, and partially divides its cavity into two passages or scalae, of which the upper is named the scala vestibuli, while the lower is termed the scala tympani. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the hamulus (hamulus laminae spiralis), which assists in forming the boundary of a small opening, the helicotrema, by which the two scalae communicate with each other. From the canalis spiralis modioli numerous foramina pass outward through the osseous spiral lamina as far as its outer or free edge. In the lower part of the first turn a second bony lamina (lamina spiralis secundaria) projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the fissura vestibuli, is seen between them.

The membrana basilaris (Fig. 768) is stretched from the unattached edge of the lamina spiralis ossea to the outer wall of the cochlea. The lamina spiralis makes an incomplete septum between the scala tympani and scala vestibuli; the membrana basilaris completes the septum. Even with the perfected septum the two scalae communicate at the apex of the cochlea by means of the helicotrema.

The Fundus of the Internal Auditory Meatus (fundus meatus acustici interni).—This structure is the inner wall of the vestibule and the base of the modiolus. A transverse ridge (erista transversa) maps it off into two parts, the fossula superior and the fossula inferior. The facial area (area n. facialis) is in the anterior portion of the fossula superior. The opening seen here is the beginning of the aqueduct of Fallopii (canalis facialis) for the transmission of the facial nerve. The superior area of the vestibule (area vestibularis superior) is the posterior portion of the fossula superior. Here the nerves perforate which supply the utricle and the ampullae of the superior and external semicircular canals (Cunningham). The area cochleae is the anterior portion of the fossula inferior. In it is the canalis centralis for the nerve-fibres to the apical turn of the cochlea; and the tractus spiralis foraminosa for the transmission of nerves to the first turn and a half of the cochlea. The
in inferior area of the vestibule (area vestibularis inferior) is back of the area cochleae and a ridge separates the two. It transmits nerves to the sacule. At the posterior part of the fossula inferior is a solitary foramen, the foramen singulare, which transmits nerves to the ampulla of the posterior semicircular canal.

The Membranous Labyrinth (Labyrinthus Membranaceus) (Figs. 771, 772).

The membranous labyrinth is contained within the bony cavities just described, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the perilymph or liquor Cotunnii (perilympba). It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the endolymph (endolympba), and on the sac the ramifications of the auditory nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the utricle and the sacule.

**Fig. 772.—The membranous labyrinth (enlarged).**

The Utricle (utriculus).—The utricle is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica and the part below it. The highest portion of the utricle is called the recess (recessus utriculi); it is placed in the elliptical recess, and opening into it are the ampulla of the superior and external semicircular canals. The central portion of the recess of the utricle receives upon the side the external semicircular canal. This opening has not an ampulla. The superior sinus is a prolongation upward and backward from the central portion of the utricle and in the superior sinus the crus commune and the superior and posterior semicircular canals open. The lower and inner portion of the utricle is the inferior sinus, and into it the ampulla of the posterior semicircular canal opens. The floor and anterior wall of the recess of the utricle are much thicker than elsewhere, and form the macula acustica utriculi, which receives the utricular filaments of the auditory nerve and has attached to its internal surface a layer of calcareous particles which are called otoliths. The cavity of the utricle communicates behind with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal (ductus utriculosaccularis), which joins with a canal from the sacule, the ductus endolymphaticus. The utricle is joined to the bony wall by numerous fibrous bands.
The Saccule (sacculus).—The saccule is the smaller of the two vesicular sacs; it is globular in form, lies in the elliptical recess near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the macula acustica sacculi, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall is given off a canal, the ductus endolymphaticus. This duct passes along the aquaeductus vestibuli and ends in a blind pouch on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. The upper extremity of the saccule looks upward and backward and forms the sinus utriculare sacculi. This lies in contact with but is not a part of the wall of the utricle. The vestibule contains the closed end of the ductus cochlearis. This is known as the caecum vestibulare. The ductus cochlearis lies below the saccule in what Reichert described as the recessus cochlearis, and it enters the spiral canal. From the lower part of the saccule a short tube, the canalis reuniens of Hensen (ductus reuniens [Hensen]), passes downward and outward to open into the ductus cochlearis. The saccule is held in position by numerous fibrous bands which pass between the saccule and the bony wall.

The Membranous Semicircular Canals (ductus semicirculares).—The membranous semicircular canals are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and present at one end within the osseous ampulla a membranous ampulla. These ampullae are called ampullae membranaceae. The canals open by five orifices into the utricle, one opening being common to two canals. In the ampullae the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the septum transversum, in which the nerves end.

The membranous canals are attached here and there to the bone by numerous fibrous bands, the so-called ligaments (ligamenta labyrinthi canaliculorum).

Structure.—The walls of the utricle, saccule, and membranous semicircular canals consist of three layers. The outer layer is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and pigment-cells analogous to those in the pigment coat of the retina. The middle layer, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The inner layer is formed of polygonal nucleated epithelial cells. The raphé of each semicircular canal is a line upon the concave side of the canal. Along the raphé the height of the epithelial cells is distinctly increased. In the ampullae adjacent to the cristae acusticae the cells are cylindrical and constitute the plana semilunata. In the maculae of the utricle and saccule, and in the transverse septa of the ampullae of the canals, the middle coat is thickened and the epithelium is columnar, is increased in height, and passes into the neuro-epithelium. The neuro-epithelium consists of supporting cells and hair-cells.

1. The supporting cells are long, wider at the ends than in the centre, contain an oval nucleus, and the lower end of the cell is fissured.

2. The hair-cells are columnar, with bulged lower ends and free upper ends. The bulged lower ends, each of which contains a spherical nucleus, do not reach higher than the middle of the epithelial layer. Each free upper end is surmounted by a long, tapering filament. These filaments constitute auditory hair, and they project into the cavity. The filaments of the auditory nerve enter these parts, and, having pierced the outer and thickened middle layer, they lose their medullary sheath, and their axis-cylinders divide into three or four branches at the larger and deeper ends of the hair-cells. These branches form a horizontal plexus
(stratum plexiforme). "These surround the hair-cells like the calyx of a flower, and give off ascending branches, which, however, do not reach the surface. In this way one branch usually comes in contact with many hair-cells."

Numerous small prismatic bodies termed **statoliths, otokonien crystals** or **otoliths**, and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, are contained in the walls of the utricle and saccule opposite the distribution of the nerves. The membrane is

---

1 Histology and Microscopic Anatomy. By Dr. Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.
called the *otolith membrane*. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullae of the semicircular canals. The conical thickening in the ampulla corresponds to the otolith membrane and is called the *cupola*.

The **Membranous Cochlea Ductus Cochlearis or Scala Media** consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall. It begins as a blind end in the recessus cochlearis of the vestibule. This beginning is the *caecum vestibulare*. It ascends inside the bony cochlea and terminates at the apex of the cochlea by a blind end, the *lagena* (caecum cupulare). The manner in which it is formed will now be described.

The osseous spiral lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. A membrane, the **basilar membrane** (membrana basilaris) (Fig. 773), stretches from its free edge to the outer wall of the cochlea, and completes the roof of the scala tympani. A second and more delicate membrane, the **membrane of Reissner** (membrana vestibularis [Reissneri]) (Fig. 773), extends from the thickened periosteum covering the lamina spiralis ossea to the outer wall of the cochlea, to which it is attached at some little distance above the membrana basilaris. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the **membranous canal of the cochlea** (ductus cochlearis or scala media) (Fig. 774). It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and its floor by the membrana basilaris, and the outer part of the lamina spiralis ossea, on the former of which is placed the organ of Corti. Reissner's membrane is thin and homogenous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, which forms the outer wall of the ductus cochlearis, is greatly thickened and altered in character, forming what is called the **spiral lamina of the cochlea** (ligamentum spirale cochleae) (Fig. 773). It projects inward below as a triangular prominence, the *crista basilaris*, which gives attachment to the outer edge of the membrana basilaris, and immediately above which is a concavity, the *sulcus spiralis externus* (Fig. 773). The upper portion of the ligamentum spirale contains numerous capillary loops and small blood-vessels, and forms what is termed the *stria vascularis*. The stria is limited below by a prominence (*prominentia spiralis*), in which a blood-vessel (*vas prominens*) is distinctly visible.

The **lamina spiralis ossea** (Fig. 774) consists of two plates of bone extending outward; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the *limbus laminae spiralis*, and this terminates externally in a concavity, the *sulcus spiralis internus*, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the *labium vestibulare*; the lower part, prolonged and tapering, is called the *labium tympanicum*, and is perforated by 4000 foramina (*foramina nervosa*) for the passage of the cochlear nerves. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free margin of the
THE MEMBRANOUS LABYRINTH. 1173

labium, and have been named by Huschke the auditory teeth. There are 7000 auditory teeth. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the zona arcuata or zona tecta (Fig. 773); it supports the organ of Corti. The outer is thicker and striated, and is termed the zona pectinata. The under surface of the membrane is covered by a layer of vascular connective tissue. One of these vessels is somewhat larger than the rest, and is named the vas spirale (Fig. 776); it lies below Corti's tunnel.

Organ of Corti (organon spirale [Cortii]) (Figs. 773, 774, 776, and 777).—The inner part of the membrana basilaris—that is, the part directed toward the canal of the ductus cochlearis—is covered with epithelium, which is largely neuro-epithe-

lium. It forms the organ of Corti. In this lie the terminations of the cochlear nerve. It appears at first sight as a papilla, winding spirally throughout the whole length of the ductus cochlearis, from which circumstance it has been designated the papilla spiralis. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a

pianoforte. The organ of Corti consists of an *inner part* and an *outer part*. Each part contains *auditory cells* and *supporting cells*. Of these cells, the two central ones are rod-like bodies and are called the *inner and outer rods of Corti*. They are placed on the basilar membrane, at some little distance from each other, but are inclined toward each other, so as to meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the *canal or tunnel of Corti*, between them and the basilar membrane, which ascends spirally through the whole length of the cochlea.

The *inner rods* (Fig. 776), some 6000 in number, are more numerous than the outer ones, and rest on the basilar membrane, close to the labium tympanicum; they project obliquely upward and outward, and terminate above in expanded extremities which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells, *inner hair-cells* (Fig. 776), surmounted by a brush of fine, stiff, hair-like processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

The *outer rods* (Fig. 776), numbering about 4000, also rest by a broad foot on the basilar membrane; they incline upward and inward, and their upper extremity resembles the head and bill of a swan; the back of the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outward as a phalangeal process of the membrana reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the
internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the outer hair-cells, in contradistinction to the inner hair-cells above referred to. There are about 12,000 outer hair-cells, and about 3500 inner hair-cells.

The hair-cells are somewhat oval in shape; their free extremities are on a level with the heads of Corti’s rods, and from each some twenty fine hairlets project and are arranged in the form of a crescent, the concavity of which opens inward. The deep ends of the cells are rounded and contain large nuclei; they reach only as far as the middle of Corti’s rods, and are in contact with the ramifications of the nervous filaments. Between the rows of the outer hair-cells are rows of supporting cells, called the cells of Deiters; their expanded bases are planted on the basilar membrane, while their opposite ends present a clubbed extremity or phalangeal process. Immediately to the outer side of Deiters’s cells are some five or six rows of columnar cells, the supporting cells of Hensen. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen’s cells are termed the cells of Claudius. A space is seen between the outer rods of Corti and the adjacent hair-cells; this is called the space of Nuel.

The lamina reticularis or membrane of Kölliker is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of “minute fiddle-shaped cuticular structures” called phalanges, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters’s cells.

Covering over these structures, but not touching them, is the membrana tectoria or membrane of Corti (Figs. 773 and 776), which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair-cells, is a clear band, named Hensen’s stripe. Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters’s cells (Retzius).

The fibres from the cochlear nerve enter the organ of Corti as axis-cylinders, which pass directly to the deepest portions of the inner and outer hair-cells by way of the canal of Corti or by the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end on the surfaces of the hair-cells.

The inner surface of the osseous labyrinth is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and fenestra rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the aqua labyrinthi, liquor Cotunnii or perilymph (Blainville).

The scala media is closed above and below. The upper blind extremity is termed the lagena, and is attached to the cupola at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives the canalis reuniens of Hensen (Fig. 772), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.
The Arteries of the Labyrinth.—The arteries of the labyrinth are the internal auditory, from the basilar, and the stylo-mastoid, from the posterior auricular. The internal auditory divides at the bottom of the internal auditory meatus into two branches, cochlear and vestibular.

The cochlear artery divides into numerous minute branches, which enter foramina in the tractus spiralis foraminosa and course in the lamina spiralis ossea to reach the membranous structures. The largest of the cochlear branches is in the canalis centralis.

The vestibular branches accompany the nerves, and supply the membranous structures in the vestibule and semicircular canals. Two arteries go to each canal. The two vessels enter opposite extremities of the canal, and anastomose at the summit of the canal. The vestibular vessels form a minute capillary network in the substance of each membranous labyrinth.

The Veins of the Labyrinth.—The veins of the vestibule and semicircular canals, the auditory veins, accompany the arteries, and receive those of the cochlea at the base of the modiolus, to form the internal auditory vein (vv. auditivae internae), which opens into the posterior part of the inferior petrosal sinus or into the lateral sinus.

The Nerves of the Labyrinth.—The auditory nerve (n. acusticus), the special nerve of the sense of hearing, divides, at the bottom of the internal auditory meatus, into two branches, the cochlear and vestibular.

The Vestibular Nerve (n. vestibularis), the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the vestibular ganglion or the ganglion of Scarpa (ganglion vestibulare); the nerve divides into three branches which pass through minute openings at the upper and back part of the bottom of the meatus (area vestibular posterior), and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The nervous filaments enter the ampullary enlargements opposite the septum transversum, and arborize around the hair-cells. In the utricle and saccule the nerve-fibres pierce the membrana propria of the maculae, and end in arborizations around the hair-cells.

The Cochlear Nerve (n. cochlearis) gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the area vestibularis inferior, which lies at the lower and back part of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the foramen singulare.

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outward to pass between the lamellae of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the spiral ganglion or ganglion of Corti (ganglion spirale), consisting of bipolar nerve-cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centrally to the brain and the other peripherally to the hair-cells of Corti’s organ. Reaching the outer edge of the osseous spiral lamina, the nerve fibres pass through the foramina in the labium tympanicum, where they lose their axis-cylinders. They enter the organ of Corti and pass directly to the deep portions of the inner and outer hair-cells by way of the canal of Corti and the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end in the surfaces of the cells.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula, which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. In some cases the cephalo-auricular angle is almost absent; in others it is nearly
a right angle. Projecting ears and long ears are said by some observers to be more common among degenerates, criminals, and the insane than among the normal, the non-criminal, and the sane. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (haematoma auris), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for ear-rings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted are: the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, the parts being illuminated with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in nowise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly injury of the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by periostitis; by polyposis, sebaceous tumors, and exostoses. The membrana tympani, when seen in a healthy ear, "reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion." From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while near the upper part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow, a loud report, a wound, or as the result of suppuration in the middle ear.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-mandibular joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells; hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-mandibular joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the auricular branch of the pneumogastric, the auriculo-temporal, and the auriculare magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the pneumogastric, or of yawning from implication of the auriculo-temporal. No doubt also the association of earache with toothache in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal maxillary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporal lobe of the brain. Its floor is immediately above the jugular fossa and the carotid canal, the fossa being behind and the canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum from extension of the inflammation through the bony roof; thrombosis of the lateral sinus, with or without pyaemia, by extension through the floor; or mastoid abscess by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Dilator tubea muscle. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an india-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth, both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the
surgeon squeezes the bulb and the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membranes tympani can be heard by the surgeon, if the membrane is intact, sound being conveyed by means of a piece of India-rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, close to the septum, with the point touching the floor, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an India-rubber tube.

THE SKIN (INTEGUMENTUM COMMUNE).

The skin covers the body surface and is continuous with the mucous membrane at the origin and termination of the alimentary canal and at the openings of other canals. The skin is a protective coat, a regulator of body-temperature, contains multitudes of the terminations of sensory nerves, and is the seat of the organ of touch (organon tactus). These nerve-terminations are connected with nerve-fibres of temperature, pressure, and pain. Connected with the skin are sweat-glands which have important excretory functions and sebaceous glands. From its superficial part come appendages, the hairs, and nails. The skin is elastic and varies in thickness from 0.5 mm. to 4 mm. It is thinnest in the eyelids and prepuce, and thickest over the back of the neck, back of the shoulders, palms of the hands, and soles of the feet. Its color depends in part on the blood within it, and in part upon pigment. The deepest hue is about the anus, in the genital region, in the axillae, over the mammary glands, and in the parts exposed to air, light, and varied temperatures. The color varies with age, being pinkish in extreme youth and becoming yellow in old age. It varies with exposure and with climate, being deepest in those who brave all weathers and temperatures and in those who dwell beneath a tropical sun. It also varies with race, and this is so well recognized that races are classified by the color of the skin into the Black, White, Yellow, and Brown races. The color of the skin is also affected in certain diseases; being extremely pale in anaemia, brown in Addison's disease, yellow in jaundice, etc.

In most situations the skin is movable, but in some it is attached closely to underlying structures, and is consequently immovable on the scalp, the palms of the hands, the soles of the feet, and the outer portion of the pina of the ear. The skin is fairly smooth, but close examination discloses multitudes of openings, creases, furrows, depressions, folds, and hairs.

Hair-follicles open upon the surface, and the ducts of sebaceous glands and of sweat-glands perforate the skin.

About the joints are folds of skin (retinaeula cutis), and temporary folds or wrinkles are created by the contraction of superficial muscles. The facial wrinkles of advancing years are due to habitual expression and loss of skin elasticity. A dimple is a permanent pit or depression due to adhesion of the surface to parts beneath. The ridges and furrows on the palms, soles, and flexor aspects of the

![Diagram of skin and joints](image-url)
digits are permanent, and over the palmar surface of the digits they are arranged in definite forms which endure through life and are so distinctive that they have been utilized by police officials in determining the identity of individuals. These folds are due to the papillae of the skin being arranged in rows; some of the papillae proliferate, and linear depressions occur in the horny layer (Philippson).

Fig. 780.—Anterior surface.
The general course of the connective-tissue bundles of the corium, determined by the direction assumed by the linear clefts made in the skin when it is punctured by a round awl. (Langer.)

Fig. 781.—Posterior surface.

Fig. 779 shows skin ridges (cristae cutis), skin furrows (sulci cutis), furrows opposite joints due to acts of flexion, and called flexure furrows, and longitudinal furrows.

When the skin is punctured by a round awl it tends to split in a definite direction, which direction varies with the region stabbed. These clefts are known
as the lines of cleavage of Langer (Figs. 780 and 781), and depend upon the arrangement of the connective-tissue bundles of the corium. These connective-tissue bundles certainly influence the formation of folds and furrows. In many portions of the body the cutaneous surface is divided by linear furrows into irregularly shaped areas (Fig. 782). The skin consists of two layers: a superficial layer, the epidermis, and a deep layer, the corium or dermis.

The Corium, Cutis Vera, Dermis or True Skin (Figs. 783, 784, and 786) is a connective-tissue structure which arises from the mesoderm. It consists especially of connective tissue and elastic fibres; it contributes elasticity to the skin, and is the seat of the sensitive layer. The corium is composed of two layers, the reticular and the papillary.

The Deep or Reticular Layer or Tunica Propria (stratum reticulare) rests upon the subcutaneous tissue. It passes superficially into the papillary layer, and at most places into the subcutaneous tissue without a sharp line of differentiation. At some places, for instance in the nipple, the deep layer of the corium rests upon a layer of muscular fibre. In the face this muscle-fibre is striated and sends prolongations to the papillary layer; in the nipple and scrotum it is non-striated. The reticular layer is composed of bundles of white fibrous tissue, arranged in a network. In the meshes of the network are fat, blood-vessels, lymphatics, sebaceous glands, sweat-glands, and hair-follicles.

The Subcutaneous Areolar Tissue or Tela Subcutanea (panniculus adiposus) connects, the skin to the parts beneath; it is composed of bundles of connective tissue.
which cross repeatedly and form spaces. In almost all regions the spaces contain fat, but in the scrotum and external ear they do not contain fat. When the connective-tissue fibres of the panniculus adiposus are long and nearly parallel to the skin-surface the skin becomes wrinkled; when they are short and nearly at right angles to the surface, the skin cannot wrinkle.

The Superficial or Papillary Layer or Corpus Papillare of the Corium (stratum papillare) lies just beneath the epidermis, contains the papillae, and is composed of a network of fine bundles of fibrous tissue. The papillae are composed of fine strands of connective tissue and elastic tissue. They project from the corium beneath the epidermis and enter into depressions of the epidermis. They vary greatly in size, averaging \( \frac{1}{4} \) of an inch in height and \( \frac{1}{2} \) of an inch in width at the base. In the face, especially in the eyelids, they are insignificant. On the glans penis, the palms of the hands, and the soles of the feet, and in the nipples, they are large. In the palmar surfaces of the hands and fingers and the plantar surfaces of the feet and toes they produce permanent ridges (Fig. 785). A ridge is composed of two or more rows of papillae, and the ducts of sweat-glands emerge between rows of papillae, and open on the curved surface ridges (Fig. 785). Most of the papillae contain loops of capillaries, and are called vascular papillae. Some contain nerve-terminations and are called nervous papillae. Between the papillary layer of the corium and the epidermis is a very thin and structureless membrane called the basal membrane.

The Cuticle, Scarf Skin or Epidermis (Figs. 783, 784, 786, and 787).—The cuticle, scarf skin or epidermis is composed of layers of epithelium and is derived from the ectoderm. The epithelium is stratified, and there are no blood-vessels. Two layers can be readily made out, the superficial or horny layer and the deeper or Malpighian layer.

The Horny Layer (stratum corneum).—The horny layer is formed by several layers of non-nucleated scaly cells. The cells consist of keratin. The surface cells of the horny layers are being constantly rubbed off, and are being replaced by cells from the Malpighian layer, which are converted into keratin as they near the surface.
The Malpighian Layer.—The Malpighian layer of the epidermis is divided into four layers, named, from without inward, the stratum lucidum, the stratum granulorum, the stratum mucosum, and the stratum germinativum.

The Stratum Lucidum is not classified by all writers as part of the Malpighian layer. Some anatomists classify it as a separate layer. It is here regarded as the most superficial part of the Malpighian layer. It consists of several layers of flat cells, the nuclei of which are beginning to disappear. The cells contain eleidin granules. In regions where the epidermis is thin the stratum lucidum is absent.

The Stratum Granulosum consists of several layers of nucleated flat cells, containing keratohyaline granules. These granules are probably formed from the disintegrating nucleus, and in the stratum lucidum are converted into eleidin.

The Mucous Layer, the Stratum Spinosum or the Stratum Mucosum consists of numerous layers of nucleated, polygonal, spine-shaped cells known as prickle cells or finger cells. Between the cells of the stratum mucosum are spaces containing pigment granules and leukocytes. Processes from the prickle-cells join adjacent cells. This layer contains numerous connective-tissue fibres arranged in a network, and known as epidermic fibrils.

The Stratum Cylindricum or Stratum Germinativum is composed of cylindrical or prickle-cells, the points of which are directed downward. Fine fibrils pass up from the corium between the cells, and there is cement-substance as well between them.

Pigmentation of the Skin.—As previously stated, in certain regions the skin of the white race is brown because of pigmentation (areolae, nipples, around the anus, axillae, scrotum, labia majora). This is due to pigment within the epithelial and
connective-tissue cells of the papillary layer of the corium, and in the basal cells of the epidermis. There are few or none of these pigmented cells in the stratum corneum of one of the Caucasian race.

"In negroes and other colored races the deep pigmentation is due to a similar distribution of the pigment granules in the entire epidermis; but even here the pigmentation decreases toward the surface, although the uppermost cells of the stratum corneum always contain some pigment. The nuclei of the cells are always free from coloring matter. The question as to the origin of the pigment is as yet unsolved."  

The Arteries and Veins of the Skin (Fig. 789).—The arteries supplying the skin vary in number, and vary much in size, being largest in regions exposed to pressure, as the skin of the palms, soles, and buttocks. The arteries enter the skin from a network in the subcutaneous tissue, and by an anastomosis in the deepest part of the corium form a network (rete arteriosum cutaneum). The vessels send branches to the fat and to the sweat-glands. Branches from the network just described ascend and form a second network in the corium beneath the papillae. This is called the subpapillary network (rete arteriosum subpapillare). From this network fine capillary vessels pass into the papillae, forming, in the smaller papillae, a single capillary loop, but in the larger a more or less convoluted vessel. From this network branches go to the hair-follicles and sebaceous glands. The blood from the papillae passes into a plexus (rete venosum) beneath the papillae. This communicates with another plexus (rete venosum), between the corium and subcutaneous tissue. In some regions one or more retia are interposed between these two. The veins from the sweat-glands, sebaceous glands, superficial fat, and hair-follicles are received by the retia venosa. From the deepest rete veins pass to the subcutaneous tissue, and these veins enter the large subcutaneous veins.

The Lymphatics of the Skin.—There are numerous lymphatics supplied to the skin which form two networks, superficial and deep, communicating with each other and with the lymphatics of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The Nerves of the Skin.—The nerves of the skin terminate partly in the epidermis (Figs. 783 and 787) and partly in the cutis vera (Fig. 783). The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies (Fig. 783), in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine about the follicle in a circular manner.

Fig. 789.—The distribution of the blood-vessels in the skin of the sole of the foot. (Spalteholz.)
manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The Appendages of the Skin.

The appendages of the skin are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The Nails (ungues) (Figs. 790, 791, 792, 793, 794, and 795).—The nails are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within. Its chief mass, called the body (corpus unguis), lies upon the nail-bed. The free edge is called the margo liber. Each lateral margin (margo lateralis), like the proximal short edge of the nail (margo occultus), lies in a groove of the cutis, the ungual fold (sulcus matricis unguis). The ungual wall (vallum unguis) overlies the lateral and posterior edges. The nail is implanted by means of a portion, called the root (radix unguis), into a groove in the skin. The root is beneath the ungual wall and is composed of cells which have not yet become horny. It is white in color. The nail has a very firm adhesion to the cutis vera, being accurately moulded upon the surface of the true skin, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the matrix (matrix unguis), because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of longitudinal ridges (cristae matricis unguis), which are very vascular, and the color is seen through the transparent tissue. Behind this, near the root of the nail, the papillae are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the lunula on account of its crescentic shape.
The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of the nail root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and the horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely

limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form, and finally become closely compacted together into a firm, dense, horny texture. In chemical composition the
nails resemble the upper layers of the epidermis, containing, however, a somewhat larger proportion of carbon and sulphur (Mulder).

The Hairs (pili) (Figs. 784, 786, 788, 796, 797, and 798).—The hairs are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, the vermilion borders of the lips, the dorsal surfaces of the phalanges, the nipples, the inner surface of the prepuce, and the glans penis. Hairs include hairs of the head (capilla); of the eyebrows (supercilia); of the beard (barba); of the ears (tragi); of the nostrils (vibrissae); the eyelashes (cilia); hairs of the axilla (hirci); pubes (pubes); and the small hairs of the skin or woolly hairs (lanugo). They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened. The hairs are usually oblique to the surface from which they arise (Fig. 784). Their direction depends upon the region from which they spring, being fairly regular in certain regions. Thus are formed hair-streams (flu-mina pilorum) and hair-whirlpools (vortices pilorum).

A hair consists of the root, the part implanted in the skin; the shaft or stem, the portion projecting from its surface; and the point.

The Root of the Hair (radix pili) presents at its extremity a bulbous enlargement, the hair-bulb (bulbus pili) (Figs. 786 and 796), which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the hair-follicle (folliculus pili) (Figs. 784 and 788). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue (Fig. 786). The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hair—to become dilated at its deep extremity or fundus (fundus folliculi pili), where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (Figs. 786, 788, 796, and 797). At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, the hair-papilla (papilla pili) (Figs. 796 and 797),
similar in every respect to the papillae found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and is probably supplied with nervous fibrils. In structure the hair-follicle consists of two coats—an outer or dermic, and an inner or epidermic (Figs. 796 and 798).

The Outer or Dermic Coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and is supplied by numerous minute nervous filaments. It consists of three layers. The most internal, the cuticular lining of the follicle, consists of a hyaline basement-membrane, the hyaline layer, having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is the inner fibrous layer, a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is the outer fibrous layer, a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

The Inner or Epidermic Layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the root-sheath. It consists of two strata, named respectively the outer and inner root-sheaths; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The inner root-sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened nucleated cells, known as Huxley's layer; and finally of a single layer of horny oblong cells without visible nuclei, called Henle's layer.

The hair-follicle contains the root of the hair, which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-

---

Fig. 797.—Vertical section through the skin of the head. The hairs of the head in longitudinal section. (Toldt.)
granules, which give rise to the color of the hair. It occasionally happens that these pigment-granules completely fill the cells of the medullary substance in the centre of the bulb, which gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The Stem or Shaft of the Hair (scapus pili) (Fig. 796), consists of a central pith or medulla, the fibrous part of the hair, and the true cuticle externally. The medulla (substantia medullaris pili) occupies the centre of the shaft and ceases toward the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is found in the shafts of all thick hairs and in the deeper parts of the root of most hairs. It is more opaque and deeper colored when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-bubbles. The fibrous portion or cortical substance of the hair (substantia corticalis pili) constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair or minute air-bubbles in white hair. In addition to this there is also a

diffused pigment contained in the fibres. The cells which form the outer hair membrane or true cuticle (cuticula pili) consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed arrectores pili (mm. arrectores pilorum) (Figs. 784 and 796). They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action elevate the hair.¹ When the hair is elevated a depression forms over the seat of origin of the muscle, and the parts about the hair are elevated. This condition is known as goose-skin. It is probable that the contraction of these muscles aids in emptying sebaceous glands.

Blood-vessels and Nerves (Fig. 786).—A hair-follicle possesses a rich network of capillaries about the hyaline membrane, and capillary loops pass to the papilla.

¹ Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.—Ed. of 18th English edition.
We have little knowledge as to nerve-terminations of the human hair. "In other mammals the nerves end below the sebaceous glands. Medullated fibres lose their medullary sheaths, divide, and penetrate to the hyaline membrane. Here some of the branches encircle the hair, while others end freely on the hyaline membrane as naked axis-cylinders. These branch regularly and run parallel to the long axis of the hair."  

The **Sudoriferous or Sweat-glands** *(glandulae sudoriferae)* (Figs. 783, 784, 786, 788, and 797).—The sudoriferous or sweat-glands are the organs by which a large portion of the aqueous and gaseous materials is excreted by the skin. They are found in almost every part of this structure, being absent on the red border of the lips, the glans penis, and inner surface of the prepuce. On the eyelids they are somewhat modified, and are called **ciliary glands** *(glandulae ciliares* [Molli]); about the anus they are extremely large, and are called **circumanal glands** *(glandulae circumanales)*. The sweat-glands are situated in small pits below the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent **duct** *(ductus sudoriferus)* proceeds upward through the corium and cuticle. The duct in the corium has true walls; in the epidermis it has not individual walls, but is simply an epidermic tube. It becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture *(porus sudoriferus)*. The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, the epidermis is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the flow of perspiration is copious, as in the axillae, where they form a thin, mamillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved surface ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of $\frac{1}{55}$ of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin.

The wall of the tubercle of the secreting coil is lined with cubical epithelial cells, external to these is a layer of smooth muscle-cells, and more externally a layer of connective tissue, the **membrana propria**. The duct in the corium, in contrast to the secreting coil, has no layer of muscle-cells, but instead a second layer of epithelial cells covered by connective tissue. As previously stated, the duct becomes spiral in the epidermis, its own wall disappears, and the channel is bounded by epidermic cells.

**Blood-vessels and Nerves.**—The blood-vessels are branches from the subcutaneous vessels and the arterial plexus of the deep part of the corium. Numerous
non-medullated nerve-fibres lie upon the membrana propria of a sweat-gland. From them fibrils pass inward and terminate by end-bulbs upon the cells of the gland.

The Sebaceous Glands (glandulae sebaceae).—The sebaceous glands are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, and are usually connected with hair-follicles. This connection is so common that they are sometimes called hair-follicle glands. They are found in some regions which are devoid of hairs—the vermillion borders of the lips, the labia minora, the glans penis, and prepuce. These glands are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear; but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, in number, as a rule, from two to five, but in some instances may be as many as twenty. They are composed of a transparent, colorless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their débris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.
THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food (apparatus digestorius) consists of the alimentary canal and of certain accessory organs.

THE ALIMENTARY CANAL.

The alimentary canal is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course; at its commencement, the mouth, we find provision made for the mechanical division of the food (mastication), and for its admixture with a fluid secreted by the salivary glands (insalivation); beyond this are the pharynx and the oesophagus, the organs which convey the food (deglutition) into that part of the alimentary canal, the stomach, in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines the nutritive principles of the food, the chyle, are separated, by its admixture with the bile, pancreatic and intestinal fluids, from that portion which passes into the large intestine, most of which is expelled from the system.

THE MOUTH, ORAL OR BUCCAL CAVITY (CAVUM ORIS).

The mouth is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication and insalivation of the food take place (Figs. 799, 818, and 824).

The aperture of the mouth (rima oris) is bounded by the lips. The angle of the mouth (angulus oris) is formed on each side by the meeting of the upper and lower lips (commissura labiorum). When at rest with the lips in contact, the rima is a slightly curved line. Every movement which the lips make alters the shape of the rima. When the mouth is closed the floor and roof are usually in contact and its sides are approximated to the dental arches. The mouth consists of two
parts: an outer, smaller portion, the **vestibule**, and an inner, larger part, the **cavity proper of the mouth**.

**The Vestibule** (*vestibulum oris*).—The vestibule is a slit-like space, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. Above and below it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid glands, and communicates, when the jaws are closed, with the cavum oris by an aperture on each side behind the wisdom teeth.

**The Cavity of the Mouth Proper** (*cavum oris proprium*).—The cavity of the mouth proper is bounded laterally and in front by the alveolar arches with their contained teeth; behind it communicates with the pharynx by a constricted aperture termed the *isthmus faucium*. It is roofed in by the hard and soft palate. The greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual glands.

**The Mucous Membrane.**—The mucous membrane lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

**The Lips (Labia Oris).**

The lips are two fleshy folds which surround the orifice of the mouth, formed externally by integument and internally by mucous membrane, between which are found the Orbicularis oris muscle (Fig. 263), the coronary vessels (Fig. 395), some nerves (Fig. 395), areolar tissue, and fat, and numerous small labial glands. The upper lip is called the **labium superius**; the lower lip is called the **labium inferius**. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the frenulum (*frenulum labii superioris* and *frenulum labii inferioris*). The frenulum labii superioris is the larger of the two. On each side, external to the angle of the mouth, the lips become continuous (*commissura labiorum*).

**The Labial Glands (glandulae labiales)** (Fig. 395).—The labial glands are situated between the mucous membrane and the Orbicularis oris muscle around the orifice of the mouth. They are rounded in form, about the size of small peas, and their ducts open by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.
THE TEETH

1195

The Cheeks (Buccae).

The cheeks form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The Mucous Membrane.—The mucous membrane lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland (ductus parotideus [Stenonis]) (Fig. 824.) The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz., the Zygomatici, Risorius Santorini, and Platysma myoides.

The Buccal Glands (glandulae bucales).—The buccal glands are placed in the submucous tissue between the mucous membrane and Buccinator muscle; they are similar in structure to the labial glands, but smaller. Four or five glands of larger size than the previously mentioned glands are placed beneath the mucous membrane in the neighborhood of the last molar tooth. They are called the molar glands (glandulae molares). Their ducts open into the mouth opposite the last molar tooth.

The Gums (Gingiva).

The gums are composed of a dense fibrous tissue closely connected to the periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillae; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

The Teeth (Dentes).

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the temporary, deciduous or milk teeth. The second set are named permanent.

The temporary teeth are twenty in number—four incisors, two canine, and four molars in each jaw (Figs. 800 and 817).

The permanent teeth are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspids, and six molars in each jaw (Figs. 802 and 806).

General Characters (Fig. 807).—Each tooth consists of three portions; the crown or body (corona dentis), projecting above the gum; the root or fang (radix dentis), entirely concealed within the alveolus; and the neck (collum dentis), the constricted portion, between the root and crown.

Surfaces.—The surfaces of a tooth are named thus: that which comes in contact with the teeth of the opposite jaw is the grinding or masticating surface (facies masticatoria); that which touches the next tooth in the same row is the contact surface (facies contactus). That surface which is toward its predecessor is called the proximal surface (in incisors and canines, facies mediale; in molars and premolars, facies anterior). That surface which is toward its successor is called the distal surface (in incisors and canines, facies lateralis; in molars and premolars, facies posterior). That which looks toward the lips and cheek is the labial or buccal surface (facies labialis). That toward the tongue is the lingual surface (facies lingualis). In part this method of designation applies to the roots as well as to the crowns of teeth.
The Roots of the Teeth.—The roots of the teeth are firmly implanted within the sockets or alveoli of the jaws (alveoli dentales) (see pp. 109 and 124). These depressions are lined with periosteum, called the pericementum, which is reflected on to the tooth at the point of the root and covers it as far as the neck. This is the root membrane (periostum alveolare). At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Temporary, Deciduous or Milk Teeth (dentes decidui) (Figs. 800, 801, and 817).—The temporary or milk teeth are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The hinder of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

Permanent Teeth (dentes permanentes) (Figs. 802, 803, 804, and 806). The Incisors (dentes incisivi).—The incisors or cutting teeth are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.

The crown is directed almost vertically and is spade-like in form; it has the form of a truncated cone whose top has been compressed into a sharp horizontal cutting
edge. Before being subjected to attrition this edge presents three small elevations. The labial surface is convex, and marked by free longitudinal ridges extending from the edge tubercles toward the neck of the tooth. The lingual surface is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the cingulum or basal ridge. The mesial and distal surfaces are triangular, the apex of the triangle being at the cutting edge. The neck of the tooth is constricted. The root is long, single, and has the form of a transversely flattened cone, thicker before than behind. The root may be curved.

The Incisors of the Upper Jaw are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the lateral incisors. They are directed obliquely downward and forward.

The Incisors of the Lower Jaw are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the teeth. The roots of these teeth are flattened laterally.

The Canine Teeth or Cuspidati (dentes canini).—The canine teeth are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and each causes a well-marked prominence of the process at the place of insertion.

The crown is large, of spear-head form, and its very convex labial surface is marked by three longitudinal ridges. The concave lingual surface is also marked by three ridges which unite at a basal ridge. The point or cusp is longer than in the other teeth, and is the point of division between a short mesial and a long distal cutting edge. These two edges form an obtuse angle with each other.

The root is single, oval, or elliptical on transverse section, and is longer and more prominent than the roots of the incisors.

The Upper Canines or cuspids, vulgarly called the eye teeth, are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The Lower Canines, vulgarly called the stomach teeth, have the general form of the upper cuspids, but their lingual surfaces are much more flattened, owing to-
the absence of the elevations marking the upper. Their roots are more flattened and may be bifid at their apices.

The Bicuspid Teeth or the Premolars (dentes premolares).—The bicuspid teeth are eight in number, four in each jaw; they are placed distal to the cuspid teeth, two upon each side of the jaw. They are double cuspids in form.

The crown is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspid are not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—i. e., it is usually tricuspid. The necks of the teeth are oval; the roots are single and laterally compressed, that of the first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series. The roots of the lower bicuspid are less compressed and more rounded.

The Molar Teeth, the Multicuspidati or Grinders (dentes molares).—The molar teeth are the largest and strongest teeth of the denture. They are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The crowns are cuboidal in form, are convex buccally and lingually; they are flattened mesially and distally. They are formed by the fusion of three primitive cuspid in the upper and four in the lower. To these are added in the first and second upper molars a disto-lingual tubercle, and in the first and third molars of the lower jaw a disto-buccal tubercle. The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form. The roots of the upper molars are three in number—one large lingual or palatal root, and two smaller buccal roots. In the lower molars, two roots are found, a mesial and a distal, each of which is much flattened from before backward.

The First Molar Teeth are the largest of the dental series; they have four cusps on the upper and five in the lower—three buccal and two lingual.

The Second Molars are smaller; the crowns of the upper are compressed until the disto-lingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle.

The Third Molars are called the wisdom teeth or dentes sapientae (dentes serotini), from their late eruption; they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together, and curve backward.

Arrangement of the Teeth.¹—The human teeth are arranged in two parabolic arches, the upper row or arch (arcus dentalis superior) being larger, its teeth overlapping the lower row or arch (arcus dentalis inferior). The average distance between the centres of the condyles of the inferior maxillary bones is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle indicated is included in it; the range of size is between three and one-half and four and one-half inches.

Owing to the smaller sizes of the lower incisors, the teeth of the lower jaw are each one-half a tooth in advance of its upper fellow, so that each tooth of the dental series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 805 and 806).

The grinding faces of the upper bicuspid and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve, the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth

¹ After Dr. W. G. A. Bonwill.
to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average of 35 degrees from the horizontal plane.¹ When the lower jaw is advanced until the cutting edges of

¹ W. E. Walker, Dental Cosmos, 1896.
the incisors are in contact, the jaws are separated, but at the highest point of the lower arch its third molar advances, and meets and rests upon a high point, the second molar of the upper arch, and thus undue strain upon the incisors is obviated.

In the lateral movements of the mandible but one side is in effective action at one time; the oblique positions of the cusps of the opposite teeth are such that when either side is in action the other is balanced at two or more points.

There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the mandible, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before backward, and have a preponderance of the direct over the oblique muscles of mastication, and vice versa; teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the heads of the mandible.

**Structure of the Teeth. The Dental Pulp (pulpa dentis).** — A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth. Processes of the chamber pass from its body, one for each root and down each root, and open at the apex by a minute orifice. This cavity is known as the *pulp-chamber* or *pulp-cavity* (cavum dentis) (Figs. 807 and 808). The minute canal in each root is called the *pulp-canal* or *root-canal* (canalis radicis dentis). The foramen at the apex of the root is the *apical foramen* (foramen apicis dentis). The cavity contains a soft, vascular, and sensitive organ called the *dental pulp* (pulpa dentis). It is made up of fibrous cellular connective tissue, the fibres of which are extremely fine, and contains numerous blood-vessels and nerves, which enter by way of the apical foramina. It has not been proved that there are lymphatics in the dental pulp, although some authors assert that they exist (Wagnermann and others). It seems to have been proved that the spaces between the fibres of the pulp communicate with the lymphatic system. The periphery of the pulp is bounded by a layer of cells arranged like columnar epithelium, each cell sending one or more branched processes through the basic substance
of the dentine. These processes constitute the **dentine fibres**. Other processes come off from the cells which pass in the direction of the pulp and surround it. The cells at the periphery of the pulp are the **dentine-forming cells**, the **odontoblasts of Waldeyer**. The blood-vessels break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve-fibrils break up into numberless non-medullary filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts.

The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillae are in the direction of the axis of the root.

**The Solid Portion of the Tooth.**—The section will exhibit three hard tissues in a tooth: one, the **proper dental substance**, forming the greater mass of the tooth; hence its name **dentine** or **ivory**. The dentine upon the exposed crown is sheathed by a layer called the **enamel**; the dentine of the root is enclosed in a distinct tissue, the **cementum** or **crusta petrosa**; both cementum and enamel are thinnest at the neck and thickest upon their distal portions.
The Ivory or Dentine (substantiae eburnea) (Figs. 808, 809, 810, and 811) forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in the fact that it does not contain cells placed in cavities, but the cells lie in the periphery of the pulp, against but not in the dentine. The dentine contains the processes of the cells, which are known as dental or dentinal fibres. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having distinct parietes. They are called the dentinal tubuli or dental canals, and are embedded in a dense homogeneous substance, the intertubular tissue.

The dentinal tubuli (canaliculi dentales) (Fig. 811) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies; they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and toward the lower part of the root they are inclined downward. The tubuli, at their commencement, are about \( \frac{1}{4} \) of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the root, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the pulp the lateral branches are few and are almost at right angles to the canals. Nearer the periphery the lateral branches are more numerous, and they come off at acute angles. The terminations of the chief canals at the periphery vary. In the crown they break up into branches like fingers just beneath the enamel. Some of these finger-like branches leave the dentine and enter the cement substance between enamel prisms. The majority of the chief canals end in blind extremities at the margin of the enamel and do not enter this structure. In the lower portion of the tooth the chief canals do not emerge from the dentine, but end at the margin of the cement in blind extremities. They may reach the spaces of the granular sheath. Near the periphery of the dentine of the crown the finer ramifications of the tubuli pass through a layer of irregular branched spaces which communicate with each other. These are called the interglobular spaces of Czermak (spatia interglobularia) (Fig. 811, J). These spaces are gaps in the dentine due to failure of calcification and are filled with uncalcified dentine. The outer part of the dentine in the lower portion of the tooth contains a layer of interglobular spaces known as the granular layer or granular sheath of Tomes. The dentinal tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the processes of the cells of

---

**Fig. 811.**—Ground-section through the root of a human premolar. D, dentine; K, cement corpuscles; O, osteoblasts; Ep., remains of Hertwig's epithelial sheath; 200 diameters; J, interglobular spaces. (Köse.)
the pulp-tissue already mentioned, and first described by Mr. Tomes and named Tomes's fibres or dentinal fibres. These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory around the canals there is a tissue which is markedly resistant to the action of acids—the dentinal sheath of Neumann.

The intertubular substance or tissue is translucent and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubules. These laminae show the method of growth to be by deposition of successive strata of dentine. Fibrils have been found in the matrix of the intertubular substance, and are probably continuous with the dentinal fibres of Tomes. In a dry tooth a section of dentine often displays a series of lines—the incremental lines of Salter—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line. (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the interglobular spaces already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the concentric lines of Schreger, and are due to the optical effect of simultaneous curvature of the dentinal tubules.

**Fig. 812.—Enamel prisms (330 diameters). A, fragments and single fibres of the enamel isolated by the action of hydrochloric acid. B, surface of a small fragment of enamel, showing the hexagonal ends of the fibres.**

**Chemical Composition.**—According to Berzelius and Bibra, dentine consists of twenty-eight parts of animal and seventy-two of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate of calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The Enamel (substantia adamantina) (Figs. 808, 810, and 812) is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms known as enamel fibres or enamel prisms (prismata adamantina) (Fig. 812). In general, they lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and
forming the free surface of the crown by the other extremity. There are occasional collections of prisms which run diagonally. The prisms are directed vertically on the summit of the crown, horizontally at the sides; they are about the $\frac{1}{3}$ of an inch in diameter, and pursue a more or less wavy course. By reflected light radial striations are visible. These are Schreger’s lines, and are due to the fact that the prisms take an undulatory course and those of two layers may have opposite directions. Another series of lines, having a brown appearance from pigmentation, and denominated the parallel striae or brown striae of Retzius or the colored lines, are seen on a section of the enamel. These lines are concentric and cross the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 808). The enamel prisms are themselves calcified and are fixed to each other by a very small amount of cement substance. Numerous minute interstices intervene between the enamel-fibres near their dentinal surface. It is noted that some of the dentinal canals at the crown penetrate a certain distance between the rods of the enamel (Fig. 810). No nutritive canals exist in the enamel, except the very few dentinal canals which at the crown penetrate a short distance, and these are found only in a small area.

**Chemical Composition.**—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists of the phosphate and the carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The enamel of a recently erupted tooth is covered by a membrane, the thickness of which is $\frac{1}{25}$ of an inch. It is known as enamel cuticle or Nasmyth’s membrane (cuticula dentis). It is probably the most recent, and hence an uncalcified, or partly calcified enamel layer. Some believe it to be a product of the outer layer of the cells of the enamel organ.

The CORTICAL SUBSTANCE, CEMENTUM or CRUSTA PETROSA (substantia ossea) (Figs. 808 and 811) is disposed as a thin layer on the roots and neck of a tooth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. At the neck it overlays a slight margin of enamel. In structure and chemical composition it is true bone. It contains, sparingly, the lacunae and canaliculi which characterize true bone; the lacunae placed near the surface have the canaliculi radiating from the side of the lacunae toward the periodontal membrane or dental periosteum, and those more deeply placed join with adjacent dentinal tubuli. The teeth of the young usually contain Haversian systems in the thicker portions of the cementum. The neck of the tooth does not contain lacunae. The cementum is occasionally laminated. Sharpey’s fibres (p. 37) are very numerous. Some of the lacunae of the cementum receive dentinal tubes from the dentine.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (the osteo-dentine of Owen; the secondary dentine of Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

**Development of the Teeth** (Figs. 813, 814, 815, and 816).—The teeth are an evolution from the dermoid system, and not of the bony skeleton; they are developed from two of the blastodermic layers, the epiblast and mesoblast. From the former the enamel is developed; from the latter the dentinal pulp, dentine, cementum, and pericementum. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth-formation in the human embryo is observed about the seventh week. The mucous membrane covering the embryonic jaws is seen to rise as a longitudinal ridge along the summit of each jaw. This ridge is
the maxillary rampart of Kölliker and Waldeyer. A transverse section through the jaw will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer; a corresponding epithelial growth is seen to sink as a band into the mesoblastic tissue beneath. This band is called the dental lamina or dental band. The local cell-activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the inner (toward the tongue) edge of the lamina epithelial cords are given off, ten in number, one for each temporary tooth.

Fig. 813.—Diagram of method of development of the teeth. 1. Early stage. 4. Later stage. 2, 3. Intermediate stages. a. Common dental germ. b. Special dental germ (milk). c. Special dental germ (permanent). d. Papilla. e. Dental furrow. (Gegenbauer.)

The growth of each cord continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior by swollen mature cells. The ingrowing bulb is now seen to flatten upon its lower surface, as though it had met with an outlined resistance from the mesoblastic tissue beneath. The epithelial ingrowth assumes the general form of the several teeth; it is the enamel-organ of the tooth (Fig. 813). The cellular tissue of the jaw beneath the cap of the enamel-organ grows and projects into the cap. This projection is the dentine papilla (papilla dentis). At this period the mesoblastic tissue around each enamel-organ is seen to become differentiated into fibrous tissue surrounding the enamel-organs, but at some distance from them. Islets of bone are also seen to be forming the beginning of the bony maxillae.

The indentation of the base of the enamel-organ continues until it assumes the form of the future teeth. The cells bounding the organ assumes a cylindrical form; the cells of the interior become much expanded, and irregular in size and form.

The mesoblastic tissue underlying the enamel-organ is much condensed; evidences of cellular differentiation and a vascular system appear. Bone continues to
THE ORGANS OF DIGESTION

develop until all of the tooth-follicles are embraced in a gutter of bone. From the lingual side of the cords of the temporary teeth epithelial buds are given off, which sink into the mesoblastic tissue and form the enamel-organs of the permanent teeth. The condensation of fibrous tissue continues until each embryonic tooth is enveloped in a sac, the dental sac (Fig. 814); this, together with all of its contents, is called the dental follicle.

The tooth which is undergoing development with its enamel-organ and dentine papilla is known as the tooth germ. This tooth germ is encompassed and shut off from surrounding structures by the bag of membranous structure known as the dental sac.

The cells of the enamel-organ now undergo a series of differentiations: the inner layer, arranged as columnar epithelium, are the enamel cells, or ameloblasts. The layer is called the ameloblastic or enamel-forming layer (Figs. 814 and 815). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of their appearance when seen in section this portion of the organ is called the enamel jelly or the stellate reticulum. The layer of cells immediately contiguous to the ameloblasts form a layer called the stratum intermedium (Fig. 815 A, D).

The enclosed mesoblastic papilla (the future dental pulp) has its peripheral cells, which are called odontoblasts, differentiated into columnar bodies disposed as a layer, each cell having a large nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood-supply. The bony alveolar walls are well outlined, and evidences of a periosteum appear (Figs. 814 and 815).

Development of Enamel (Fig. 815 B).—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calcoglobulin), the basis of all the calcified tissues. At the ends of the ameloblasts,
next to the dentine, the secretion of calco-globulin is deposited, and into the plastic mass the enamel-globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.  

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular globules, and irregular masses of it are extruded as cementing substance. The deposition continues until the enamel-cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel-rods. At the completion of amelification the ameloblasts are partially calcified and form the enamel cuticle or Nasmyth's membrane (cuticula dentis).

**Formation of Dentine.**—The layer of columnar cells bounding the periphery of the pulp, the odontoblasts, are in apposition with a plexus of capillary vessels (Fig. 816). Each cell is a secreting body which selects the material for dentine-building. Against the layer of ameloblasts covering the dental papilla the odontoblasts deposit globules, of the calcium albuminate, and receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit. These are known as Tomes's fibres. The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue. The layer of formative cells remains constant. The remains of the dentine papilla constitute the pulp and lie in the pulp-cavity (p. 1200).

**Formation of Cementum.**—Hertwig asserts that the epithelial edge of the enamel organ formed by the inner and outer epithelial layers of the organ grows downward, or rather the developing tooth grows upward until the future root-form of the tooth is outlined by a double layer of epithelial cells, constituting the root-sheath of Hertwig. The growth of the alveolar process is synchronous.

Upon the pulp side of the sheath a layer of odontoblasts is developed; upon the outer side the fibrous encasement becomes closely attached to the sheath and a layer of osteogenetic cells is differentiated. These cells are called cementoblasts. The growth of the dentine of the root is exactly similar to the growth of that of the crown. The epithelial sheath undergoes atrophic changes, leaving the epithelial whorls which remain in the pericementum. The cementum is developed as subperiosteal bone. The cementum over the apex of the root is not formed until after the eruption of the tooth.

**Formation of Alveoli.**—By the time the crowns of the teeth have formed, each is enclosed in a loculus of bone which has developed around it and at some distance from it; the loculus is open at the top toward the gums, where it is closed by fibrous tissue; the developing permanent tooth is contained in the same loculus, but is later separated from the temporary tooth by a growth of bone. The alveolar

---

1 J. L. Williams, Dental Cosmos, 1896.
process is not completed until after the eruption of the teeth. During eruption
that portion of the process overlying the crown undergoes absorption, and as soon
as the immature tooth has erupted the alveolar process is developed about the root,
whose formation is also completed after eruption.

Development of the Permanent Teeth.—The permanent teeth as regards their
development may be divided into two sets: (1) those which replace the temporary
teeth, and which, like them, are ten in number; these are the successional perma-
nent teeth; and (2) those which have no temporary predecessors, but are super-
added at the back of the dental series. These are three in number on either side
in each jaw, and are termed the superadded permanent teeth. They are the three
molars of the permanent set, the molars of the temporary set being replaced by
the premolars or bicuspids of the permanent set.

The Development of the Successional Permanent Teeth—the ten anterior ones
in either jaw—will be first considered. As already stated, the germ of each
milk tooth is a special thickening of the "free" edge of the common dental germ
or dental lamina. In like manner is formed the special dental germ of each of
the successional permanent teeth. But these thickenings are not at the "free"
edge of the dental lamina, but occur behind and lateral to each of the milk-tooth
germs (Fig. 813). There are ten of these, and they appear in order, about the
sixteenth week, on each side, the central incisor germs being the first.

These special dental germs now go through the same transformations as
were described in connection with those of the milk teeth, and the changes also
eventuate in the germs becoming enamel organs; that is, they recede into the
substance of the gum behind the germs of the temporary teeth. As they recede
they become flask-shaped, form an expansion of their distal extremity, and finally
meet a papilla, which has been formed in the mesoblast, just in the same
manner as was the case in the temporary teeth. The apex of the papilla inden-
tates the dental germ, which encloses it, and forming a cap for it, undergoes
analogous changes to those described in the development of the milk teeth, and
becomes converted into the enamel, whilst the papilla forms the dentine of the
permanent tooth. In its development it becomes enclosed in a dentinal sac which
adheres to the back of the sac of the temporary tooth. The sac of each perma-
nent tooth is also connected with the fibrous tissue of the gum by a slender band
of the gubernaculum, which passes to the margin of the jaw behind the correspond-
ing milk tooth (see above).

The Superadded Permanent Teeth—three on each side in each jaw—arise from
successive extensions backward—i.e., along the line of the jaw—of the common
dental germ from the back part of the special dental germ of the immediately
preceding tooth. During the fourth month or seventeenth week, in that portion
of the common dental germ which lies behind—i.e., lateral to the special dental
germs of the last temporary molar tooth, and which has hitherto remained unalter-
ted—there is developed the special dental germ of the first permanent molar
into which a papilla projects. In a similar manner, about the fourth month after
birth the second molar is formed, and about the third year the third molar.

Eruption.—When the calcification of the different tissues of the milk tooth
is sufficiently advanced to enable it to bear the pressure to which it will be after-
ward subjected, its eruption takes place, the tooth making its way through the
gum. The gum is absorbed by the pressure of the crown of the tooth against it,
which is itself pressed up by the increasing size of the fang. At the same time
the septa between the dentinal sacs, at first fibrous in structure, ossify and thus
form the loculi or alveoli; these firmly embrace the necks of the teeth and afford
them a solid basis.

Previous to the permanent teeth penetrating the gum, the bony partitions
which separate their sacs from the deciduous teeth are absorbed, the roots of
the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called odontoclasts, which are developed at the time in the neighborhood of the root, and the permanent teeth become placed under the loose crown of the deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth (Fig. 817).

**Calcification** of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and cuspid, about six months after birth; the bicuspid, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The **Eruption of the Temporary Teeth** commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes)—

The **Eruption of the Permanent Teeth** takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

- 6½ years, first molars.
- 7th year, two middle incisors.
- 8th year, two lateral incisors.
- 9th year, first bicuspid.
- 10th year, second bicuspid.
- 11th to 12th year, canine.
- 12th to 13th year, second molars.
- 17th to 21st year, third molars.
The palate forms the roof of the mouth; it consists of two portions, the hard palate in front, the soft palate behind.

The Hard Palate (palatum durum) (Figs. 818 and 819).—The hard palate is bounded in front and at the sides by the upper alveolar arches and gums. In front and to the sides it is continuous with the gums; behind, it is continuous with the soft palate. It is formed by the palate processes of the superior maxillary bones and the palate processes of the palate bones (Fig. 72). It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent, particularly to the front and sides, by means of a layer of fibrous tissue. Along the middle line is a linear ridge or raphe (raphe palati), which terminates anteriorly in a small papilla, the incisive papilla (papilla incisiva), corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. The incisive papilla in a recently born child is continuous with the gum and the frenulum of the upper lip. On either side and in front of the raphe the mucous membrane is thick, pale in color, and corrugated; these corrugations, which are composed of fibrous tissue, are the palatine rugae (plicae palatinae transversae). In very young children the rugae are distinct and definite. In the aged they are indistinct. Behind, it is thin, smooth, and of a deeper color; it is covered with squamous epithelium, and the fibrous tissue beneath it
contains many mucous glands, the **palatine glands** (*glandulae palatinae*). The palatine vessels and nerves lie in the fibrous tissue beneath the mucous membrane.

**The Soft Palate or Velum Pendulum Palati** (*palatum molle*) (Figs. 818, 819, and 824).—The soft palate is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position it is relaxed and pendent and its oral surface is concave, continuous with the roof of the mouth, and marked by a **median ridge** or **raphé**, which indicates its original separation into two lateral halves. Its pharyngeal surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its anterior or upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its posterior or lower border is free. The posterior portion of the soft palate is known as the **vail of the palate** (*velum palatinum*) and terminates posteriorly and externally on each side in a free margin, the posterior arch of the palate.

Hanging from the middle of its lower border is a small, conical-shaped, pendulous process, the **uvula** (*uvula palatina*). The uvula varies greatly in length in different individuals. It is composed of glands and connective tissue, contains a prolongation of the Azygos uvulae muscle and is covered with mucous membrane, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the **arches or pillars of the soft palate** or **pillars of the fauces** (*arcus palatini*).
The Anterior Pillar (areus glossopalatinus) (Figs. 818 and 824).—The anterior pillar on each side runs downward, outward, and forward to the side of the base of the tongue. These pillars are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The Posterior Pillar (areus pharyngopalatinus) (Figs. 818 and 824).—The posterior pillar on each side is nearer to its opposite arch than is the anterior pillar to its opposite. These pillars are larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the tonsils is lodged.

The space left between the arches of the palate on the two sides is called the isthmus of the fauces (isthmus fauceum). It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side by the pillars of the fauces and the tonsils. Through this isthmus the mouth communicates with the pharynx.

The Mucous Membrane of the Soft Palate.—The mucous membrane of the soft palate is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where its epithelium is columnar and ciliated. Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on the pharyngeal surface and around the uvula.

The Aponeurosis of the Soft Palate.—The aponeurosis of the soft palate is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendons of the Tensor palati muscles.

The Muscles of the Soft Palate.—The muscles of the soft palate are six on each side: the Levator palati, Tensor palati, Azygos uvulae, Palato-glossus, Palato-pharyngeus and Salpingo-pharyngeus (see pp. 403, 404, 405, and 406). The following is the relative position of these structures in a dissection of the soft palate from the posterior or naso-pharyngeal to the anterior or oral surface: Immediately beneath the pharyngeal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. This posterior fasciculus is joined by the Salpingo-pharyngeus muscle. Beneath this are the Azygos uvulae and Salpingo-pharyngeus muscles, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the Levator palati, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding around the hamular process of the internal pterygoid plate of the sphenoid bone, expands into a broad aponeurosis in the soft palate, anterior to the other muscles, which have been enumerated. Finally, we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The Blood-vessels of the Palate (Fig. 819).—The palate is supplied with blood by branches of the posterior or descending palatine branch of the internal maxillary artery (a. palatina descendens) and of the ascending or anterior palatine branch of the facial artery (a. palatina ascendens). The posterior palatine artery divides into the great and small palatine arteries (aa. palatinae major et minor), which run through the

1 According to Klein, the mucous membrane on the nasal surface of the soft palate in the fetus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.—Ed. of 15th English edition.
palatine canals and after emerging give off branches. Branches from the small palatine go to the soft palate, the large branch passes forward on the hard palate near the alveolar margin. The ascending palatine branch of the facial lies upon the medial surface of the Tensor palati muscle and is distributed to the soft palate and pharynx. A palatine vein corresponding to the descending palatine artery opens into the anterior facial vein. The pharyngeal veins also receive palatine veins.

The Nerves of the Palate.—The large posterior palatine nerve emerges from the posterior palatine canal and accompanies the posterior palatine artery. The naso-palatine nerve emerges from the foramen of Scarpa and is distributed to the anterior portion of the hard palate. The soft palate is supplied by the small posterior palatine and the accessory palatine nerves.

The Tonsil or Amygdala (tonsilla palatina) (Figs. 818 and 824).—The tonsils or amygdalae are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. A recess, the supra-tonsillar fossa (fossa supratonsillaris), may be seen, directed upward and backward above the tonsil. His regards this as the remains of the lower part of the second visceral cleft. The recess is covered by a fold of mucous membrane termed the plica triangularis. Externally the tonsil is covered with a fibrous capsule which joins the aponeurosis of the pharynx. The outer surface of the capsule is in relation with the inner surface of the Superior constrictor muscle of the pharynx, to the outer side of which is the Internal pterygoid muscle. The ascending palatine artery is close to the outer surface of the tonsil, the Superior constrictor muscle of the pharynx and the tonsillar capsule intervening. The tonsillar artery, which is sometimes a branch of the ascending palatine, is also close to the outer surface of the tonsil. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (20 to 25 mm.) distant from it. It corresponds to the angle of the lower jaw. The surface of the tonsil which looks toward the pharynx presents from twelve to fifteen orifices, each leading into a small recess or crypt (fossa tonsillaris). From the crypts numerous follicles branch out into the substance of the tonsil by means of very irregular channels. The crypts are lined with stratified pavement epithelium. The epithelium of the crypts exhibits marked degenerative changes. The degeneration causes the formation of numerous communicating spaces, which contain leukocytes and lymphocytes. The crypts are surrounded with lymphoid tissue. In this are numerous lymphoid follicles (noduli lymphatici), which are placed in the submucous tissue. These follicles are analogous to those of Peyer’s glands and consist of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion.

The Blood-vessels of the Tonsil.—The arteries supplying the tonsils are the dorsalis linguae from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal. The veins terminate in the tonsillar plexus, on the outer side of the tonsil, and the tonsillar plexus joins the pharyngeal plexus, which communicates with the pterygoid plexus of the internal jugular or facial vein.

Lymphatics of the Tonsil.—Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the submaxillary lymph glands below the angle of the jaw. From the submaxillary glands lymph passes to the deep cervical glands.

The Nerves of the Tonsil.—A branch from the glosso-pharyngeal nerve by uniting with branches of the pharyngeal plexus forms the tonsillar plexus. The pharyngeal plexus is formed by the pharyngeal branches of the glosso-pharyngeal and superior cervical ganglions and the pharyngeal branch of the vagus.
The Organs of Digestion

The Salivary Glands (Fig. 820).

Numerous glands exist in the lips, cheeks, palate, and tongue, but by the term salivary glands are usually understood the three chief glandular masses on each side of the face. These are the principal salivary glands. They communicate with the mouth, pour their secretion into its cavity, and are named respectively the parotid, submaxillary, and sublingual.

The Parotid Gland (glandulae parotis) (Fig. 646).—The parotid gland, so called from being placed near the ear (παρός, near; ὀὖς, ἀτός, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between the angle and the mastoid process: anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the two muscles.

Its anterior surface is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and superficial to the ramus over the Masseter muscle. Its outer surface is triangular and convex, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its inner surface (processus retromandibularis) extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the external carotid artery, giving off its three terminal
branches: the **posterior auricular artery** emerges from the gland behind; the **superficial temporal artery** above; the **transverse facial**, a branch of the temporal, in front; and the **internal maxillary** winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the **temporal** and **internal maxillary veins**; a branch, connecting this trunk with the internal jugular, also passes through the gland. The gland is also traversed by the **facial nerve** and its branches, which emerge at its anterior border; branches of the **great auricular nerve** pierce the gland to join the facial, and the **auriculo-temporal branch** of the inferior maxillary nerve emerges from the upper part of the gland. The **internal carotid artery** and **internal jugular vein** lie close to its deep surface. The triangular space occupied by the greater part of the gland is bounded in front by the posterior margin of the ramus of the jaw and the internal pterygoid muscle, and behind by the anterior edge of the Sternocleido-mastoid muscle, the tympanic portion of the temporal bone and the cartilaginous portion of the external auditory meatus. Its floor is formed by the anterior and posterior walls of the space which meet about the styloid process. These walls are composed of fascia derived from the deep cervical fascia. The remaining side of the space is external and is formed by fascia, derived from the deep cervical fascia and called the **parotid fascia**. This space is called the **parotid recess**. Sir Frederick Treves\(^1\) denies that the fascial covering of the space is complete. He says it is deficient above between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle. A portion of the gland does not occupy the space, but projects forward over the Masseter muscle. This projecting portion is the **facial process**.

**Lymph-glands**, known as the **parotid lymph-glands**, are in and about the parotid gland, some being embedded in the outer surface of the parotid fascia, others being in the inner surface of the fascia, others in the gland itself, particularly along the temporo-maxillary vein and external carotid artery. They receive lymph from the anterior and lateral portions of the scalp, both eyelids, a portion of the cheek, the root of the nose, the outer portion of the external ear, the soft palate, the posterior nares, and the external auditory meatus. The vessels from them empty into the superficial cervical glands and the superior deep cervical glands. Between the parotid gland and the pharynx are the **subparotid glands**. They receive lymph from the nasal fossae, naso-pharynx and Eustachian tube, and vessels from the glands take lymph to the deep cervical glands.\(^2\)

**The Duct of the Parotid Gland, called the Parotid Duct or Stenson’s Duct** (*ductus parotideus* [Stenonis]) (Fig. 820).—The duct of the parotid gland is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator muscle and the mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar tooth of the upper jaw (Fig. 824). Upon the beginning of Stenson’s duct there is often an **accessory parotid gland** (*glandulae parotis accessoria*), which is often called the **socia parotis**. It is a portion of the facial process. It is a detached portion of gland, and has a duct which opens into Stenson’s duct. This accessory gland occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

**Surface Form.**—The direction of the duct corresponds to a line drawn across the face about a finger’s breadth below the zygoma; that is, from the lower margin of the concha to midway between the free margin of the upper lip and the ala of the nose.

\(^1\) Applied Anatomy.  
\(^2\) Poirier and Cunéo, Human Anatomy.
Structure of the Parotid Duct.—The parotid duct is dense, it is of considerable thickness, and its canal is about the size of a crowquill; but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size. The duct consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Vessels and Nerves.—The arteries supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The veins empty themselves into the external jugular through some of its tributaries. The lymphatics terminate in the superficial cervical and the deep cervical glands, passing in their course through several lymphatic glands placed on the surface and in the substance of the parotid. The nerves are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculo-temporal, and great auricular nerves. It is probable that the branch from the auriculo-temporal nerve is derived from the glossopharyngeal through the otic ganglion. At all events, in some of the lower animals this has been proved experimentally to be the case.

The Parotid Capsule.—The parotid gland is enclosed by two layers of the parotid fascia (fascia parotideomasseterica), which almost completely encompass the gland. The sheath is incomplete at one area toward the pharyngeal wall (see p. 1215).

The parotid fascia comes from the deep cervical fascia. The external layer covers the gland. The internal layer lines the parotid recess. The external layer is the structure usually spoken of as the parotid fascia. Anteriorly it joins the fascia of the masseter; below it is continuous with the deep cervical fascia; above it is attached to the zygoma; behind it is adherent to the external auditory meatus and sheath of the Sternomastoid. The deep layer is adherent above to the external auditory meatus and back of the glenoid fossa; internally to the styloid process; below it is continuous with the deep cervical fascia. The stylomandibular or stylomandibular ligament comes off from the parotid fascia.

The Submaxillary Gland (glandula submaxillaris) (Fig. 820).—The submaxillary gland is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms (8 to 10 grammes). It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of the body of the mandible, and lies upon the Mylo-hyoid, Hyoglossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric muscle; behind, it is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies embedded in a groove in its posterior and upper border. A process is given off from the deep surface of the anterior portion of the gland. This is the deep process (Cunningham), and it passes with the duct beneath the Mylo-hyoid muscle.

The Duct of the Submaxillary Gland or Wharton's Duct (ductus submaxillaris [Whartoni]).—The duct of the submaxillary gland is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylo-hyoid muscle, and passes forward and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus muscle, and opens by a narrow orifice on the summit of a small papilla (caruncula sublingualis) at the side of the frenum linguae. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.
THE SALIVARY GLANDS

Vessels and Nerves.—The arteries supplying the submaxillary gland are branches of the facial and lingual. Its veins follow the course of the arteries. The lymphatics drain into the submaxillary lymph-glands. There are no lymphatic glands in this salivary gland. The nerves are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and from the lingual branch of the inferior maxillary, sometimes from the mylo-hyoid branch of the inferior dental, and from the sympathetic.

The Sublingual Gland (glandula sublingualis) (Fig. 820).—The sublingual gland is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frænum linguæ, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, above, with the mucous membrane; below, with the Mylo-hyoid muscle; in front, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; behind, with the deep part of the submaxillary gland; and internally, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton’s duct. Its excretory ducts or ducts of Rivinus (ductus sublingualis minores) are from eight to twenty in number. They open separately into the mouth back of Wharton’s duct and upon a fold of mucous membrane known as the plica sublingualis. The plica sublingualis is an elevated crest of mucous membrane caused by the projection of the gland on either side of the frænum linguæ. One or more ducts sometimes join to form a tube which opens into the Whartonian duct or remains independent, opening close to Wharton’s duct on the sublingual papilla. This single duct is called the duct of Bartholin (ductus sublingualis major).

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands (Fig. 821).—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, dividing frequently like the branches of a tree, the branches terminating in dilated ends or alveoli, on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane which is continuous with the membrana propria of the duct. It presents a peculiar reticulated
structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid which contains mucus, and such alveoli have therefore been named the *mucous alveoli*, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and alveoli of this variety have been named *serous* or *albuminous alveoli*. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both varieties of alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The *Mucous Alveoli*.—The cells in the mucous alveoli are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying between the cells and the membrana propria of the alveolus. They are termed the *crescents of Gianuzzi* or the *demilunes of Heidenhain* (Fig. 821), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

The *Serous Alveoli*.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature embedded in a closely reticulated protoplasm. The ducts which originate from the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cells next the basement-membrane is finely striated. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; they are to be found in the submaxillary, but not in the parotid.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

The *Mucous Glands*.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillae, and also along its margins as far forward as the apex. Others lie around and in the tonsil

---

1 It has been shown by Ehner that many of these glands open into the trenches around the circumvallate papillae, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.—En. of 18th English edition.
between its crypts, and a large number are present in the soft palate. These glands are of the ordinary compound racemose type. Behind the tip of the tongue on each side, external to the anterior extremity of the genio-glossus muscle, is a mucous gland, the gland of Nuhn and Blandin (glandula lingualis anterior). Its lower surface is partly covered by muscular fibres from the inferior lingualis and styloglossus muscles, and it opens by several ducts.

**Surface Form.**—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Ethiopian tribes the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro’s face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphe which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papille; the posterior third smooth and tuberculated, and covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papille which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the fraenum linguae, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this fraenum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the fraenum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the fraenum, in the floor of the mouth, is a longitudinally elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the fraenum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton’s ducts, into which a fine probe may be passed without much difficulty. By evverting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the fraena; these are not so large as the fraenum linguae. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson’s duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. These are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the isthmus of the fauces, or, as it is popularly called, “the throat.” this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting downward from the middle of its lower border is a conical-shaped projection, the uvula. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the tonsil. The extirpation of this body is not unattended with danger of hemorrhage. Dr. Weir has stated that he believes that when hemorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are
large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the pterygo-maxillary ligament, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the lingual (gustatory) nerve where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 1043). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphylorrhaphy. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and it is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebrae may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx can be ascertained.

THE PHARYNX (Figs. 818, 824, 825).

The pharynx (from φάργξ, the throat) is that part of the alimentary canal which is placed behind and communicates with the nose, mouth, and larynx. It is a musculo-membranous tube, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the level of the cricoid cartilage in front and that of the intervertebral disk between the fifth and sixth cervical vertebrae behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point, at its termination in the oesophagus. It is attached, above, to the periosteum of the petrous portion of the temporal bone and of the basilar process of the occipital bone. To the pharyngeal tubercle of the basilar process of the occipital bone the raphé of the Constrictor muscles is attached. It is bounded above by the body of the sphenoid as well as by the basilar process of the occipital; below, it is continuous with the oesophagus; posteriorly, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longi colli and Recti capitis antici muscles; this areolar tissue is contained in what is called the retro-pharyngeal space (spatia retropharyngea); anteriorly, it is incomplete, the gap being occupied by the cavities of the nose, mouth, and larynx. Anteriorly, it is attached in succession to the Eustachian tube, the internal pterygoid plate, the pterygo-maxillary ligament, the posterior termination of the mylo-hyoid ridge of the lower jaw, the mucous membrane of the mouth, the base of the tongue, hyoid bone, the thyroid and cricoid cartilages; laterally, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles. When the pharynx
is at rest the anterior and posterior walls are near together. Above the larynx they do not come in contact, but leave a channel for air; below the larynx they lie in contact, but open for the passage of food. It has seven openings communicating with it—the two posterior nares, the two Eustachian tubes, the mouth, larynx, and oesophagus. The pharynx may be subdivided from above downward into three parts, nasal, oral, and laryngeal.

**The Nasal Part** (*pars nasalis pharyngis*) (Fig. 824).—The nasal part of the pharynx or *naso-pharynx* lies behind the nose and above the level of the soft palate; it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the *posterior nares* (*choanae*) (Fig. 825) with the nasal fossae. On its lateral wall is the **pharyngeal orifice of the Eustachian tube** (*ostium pharyngeum tubae auditivae*) (Figs. 822 and 823), which presents the appearance of a vertical or triangular cleft bounded above and behind by a firm prominence. The anterior portion of the prominence (*labium anterius*) is the smaller portion. The posterior portion (*labium posterius*) is large and thick, is called the **Eustachian cushion** (*torus tubarius*), and is caused by the inner extremity of the cartilage of the tube impinging on the deep surface of the mucous membrane (Fig. 823). A vertical fold of mucous membrane, the **salpingo-pharyngeal fold** (*plica salpingo-pharyngea*) (Fig. 823), stretches from the lower part of the cushion to the pharynx; it contains the Salpingo-pharyngeus muscle. A second and smaller mucous fold may be seen stretching from the upper part of the cushion to the palate, the **salpingo-palatine fold** (*plica salpingopalatina*) (Fig. 823). Behind the orifice of the Eustachian tube is a deep recess, the **lateral recess or fossa of Rosenmüller** (*recessus pharyngeus*) (Fig. 823), which represents the remains of the upper part of the second branchial cleft. The posterior wall of the naso-pharynx is directed upward and forward, and it meets the superior wall at an angle. This rounded area of meeting is the **vault of the pharynx** (*fornix pharyngis*). On the posterior wall, at the level and above the level of the orifices of the Eustachian tubes, there is a collection of lymphoid tissue. This is particularly marked in children, and almost or quite disappears in the aged. Over it the mucous membrane is thick and in folds. This collection of lymphoid tissue is the **pharyngeal tonsil** (*tonsilla pharyngea*) (Fig. 822). The naso-pharynx communicates with the oral pharynx through an aperture between the soft palate and the posterior pharyngeal wall. This aperture is the **isthmus of the pharynx** (*isthmus pharyngonasalis*).

**The Oral Part** (*pars oralis pharyngis*).—The oral part of the pharynx reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two
pillars of the fauces, is the tonsil. A triangular area on the lateral wall is known as the **sinus tonsillaris** (Fig. 824). It is bounded anteriorly by the anterior palatine arch, posteriorly by the posterior palatine arch, and below by the side of the pharyngeal portion of the tongue.

**The Laryngeal Part** *(pars laryngea pharyngis).*—The laryngeal part of the pharynx is that division which lies behind the larynx; it is wide above where it is continuous with the oral portion while below at the lower border of the cricoid cartilage it becomes continuous with the oesophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the aryteno-epiglottidean folds. On either side of the laryngeal orifice is a recess, termed the **sinus pyri-

![Diagram](https://example.com/diagram.png)

Fig. 824.—Sagittal median section of the head and neck. The head is thrown backward into complete extension, which explains the relations between the lower jaw and the hyoid bone as seen in the figure. (Luschka.)

formis (recessus piriformis) (Fig. 824); it is bounded internally by the aryteno-epiglottidean fold, externally by the thyroid cartilage and thyro-hyoid membrane. In the anterior part of the sinus pyriformis is a fold (*plica nervi laryngei*), which passes downward and inward. Extending outward from the epiglottis on each side is a fold, the **pharyngo-epiglottic fold** (*plica pharyngoepiglottica*). This ascends in the lateral wall of the pharynx, nearly to the posterior arch of the fauces.

**Structure.**—The constrictors of the pharynx (see p. 400) are surrounded by a sheath of thin fascia, the **bucco-pharyngeal fascia** (Cunningham). Forward pro-
longations of this fascia overlay the Buccinator muscles. The connective tissue of the retro-pharyngeal space joins the bucco-pharyngeal fascia to the prevertebral fascia, and it is attached by areolar tissue to the other structures to which the pharynx is in contact (Cunningham). The pharynx is composed of three coats—fibrous, mucous and muscular.

The Pharyngeal Aponeurosis or Fibrous Coat is situated between the mucous and muscular layers. It is thick above, where the muscular fibres are wanting, and is firmly connected to the periosteum of the basilar process of the occipital and petrous portion of the temporal bones. It is united to the Eustachian tube, posterior nares, and other points which the pharynx joins. It is thicker above than below, and above the sinuses of Morgagni there is no muscular coat, and the wall of the pharynx is composed of aponeurosis and mucous membrane. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a median raphé, which gives attachment to the Constrictor muscles of the pharynx.

The Mucous Coat (tunica mucosa).—The mucous coat is continuous with that lining the Eustachian tubes, the nares, the mouth, and the larynx. In the nasopharynx it is covered by columnar ciliated epithelium; in the buccal and laryngeal portions the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose mucous glands (glandulae pharyngeae); they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or recesses, the walls

![Diagram of the pharynx](image-url)
of which are surrounded by lymphoid tissue similar to that found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the **pharyngeal tonsil** (Fig. 822). Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the **pharyngeal bursa** (*bursa pharyngea*), and was regarded by Luschka as the remains of the diverticulum, which is concerned in the development of the anterior lobe of the pituitary body. Other anatomists believe that it is connected with the formation of the pharyngeal tonsils. The **muscular coat** (*tunica muscularis pharyngis*) has been already described (p. 400). The **sinuses of Morgagni**, referred to on a previous page (p. 402 and Fig. 277), are intervals between the Superior constrictor muscles and the basilar process of the occipital bone.

**The Lymphatic Pharyngeal Ring.**—This name was applied by Waldeyer to the lymphatic structure gathered into a sort of ring about the pharynx. There are three chief collections of this tissue on each side. The first is known as the **lingual tonsil** (p. 1088); the second as the **palatine tonsil** (p. 1212); and the third as the **pharyngeal tonsil** (p. 1221).

**Surgical Anatomy of the Mouth, Cheeks, Lips, Gums, Tonsils, Palate, Salivary Glands, and Pharynx.**—The duct of a salivary gland may be blocked by a *calculus*, and the condition is often productive of severe pain.

A **wound** of Stenson’s duct or of the parotid gland may be followed by a *salivary fistula*.

The parotid recess is completely lined by fascia, except above. “Between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle there is a gap in the fascia, through which the parotid space communicates with the connective tissue about the pharynx.”

This explains why there is frequently swelling of the parotid region in post-pharyngeal abscess. A **parotid abscess** rarely bursts through the skin; it may pass into the temporal fossa, may enter the zygomatic fossa, may advance toward the mouth, pharynx, or neck. Because of the situation of the gland, a parotid abscess may cause inflammation of the temporomandibular joint or periostitis of the bone about the meatus, and may even burst into the external auditory meatus (Treves).

The facial nerve passes through the gland, and inflammation or tuberculosis of the gland may cause *facial palsy*. Some enlargements of the parotid region are due to inflammation of the parotid lymph-glands, and these glands may become *tuberculous*.

**Mumps** is characterized by acute inflammation of the parotid gland.

Various **tumors** occur in the parotid (fibroma, sarcoma, carcinoma, enchondroma, etc.). Most parotid tumors contain more or less cartilage. Complete extirpation of the parotid gland surgically is certainly extremely difficult, and Treves and others maintain that it is impossible.

**Ranula** is a salivary cyst of the floor of the mouth, due to occlusion of ducts of the sublingual gland or the duct of the submaxillary gland. **Mucous cysts** occur in the mouth. A mucous cyst of the gland of Nuhn and Blandin is on the under surface of the tongue near the apex. A dermoid cyst of the base of the tongue is occasionally encountered. It is of congenital origin.

What is known as the **sublingual bursa** is an epithelial-lined space, said to exist between the mucous membrane of the floor of the mouth and the Genio-hyo-glossus muscle. When acutely inflamed, it produces rapidly a marked swelling called *acute ranula*. Incomplete closure of the oral end of the thyro-glossal duct causes *thyro-glossal cyst*. If the oral end closes, but a portion of the duct below remains unobliterated, a thyro-glossal cyst forms. Such a cyst or fistula is always in the median line. The reader will remember that this duct runs from the foramen caecum to the isthmus of the thyroid gland.

**Hare-lip** is considered on pp. 110 and 111.

The lower lip, more commonly than any other structure, gives origin to cancer. The upper lip is not nearly so often affected. Blocking of mucous glands of the lips causes *mucous cysts*. A **scar** of the lip or about the lip disturbs this structure and pulls it far out of place. Thus great deformity is produced. *Burns* particularly induce hideous cicatrical contraction.

**Plastic operations** in this region are often successful, because of the great vascularity of the parts, and because adjacent parts admit of being stretched and pulled in.

**Cleft palate** is a by no means rare congenital deformity. The cleft is in the middle line. It may be a mere cleft of the uvula, it may be limited to the soft palate, or it may involve

---

1 Applied Anatomy. By Sir Frederick Treves.
the hard palate to but not including the alveolus. It may pass through the alveolus, but if it does so it ceases to be median at this point, and follows the line of suture between the incisive bone and the superior maxillary (pp. 110 and 111). In a complete cleft palate there is apt to be hare-lip at the end of the palate eft. This eft in the lip is not median, but is at the termination of the palate eft. If the eft of a cleft palate runs along each side of the incisive bone, the bone is isolated from the superior maxillary. In such a case double hare-lip results.

When a tonsil enlarges it projects inward. The deafness which so often attends hypertrophy of the tonsil is not due to blocking of the Eustachian orifice by the tonsil, but is due to thickening of the mucous membrane lining the tube itself. The profuse bleeding which sometimes follows an operation for the removal of the tonsil is very seldom due to injury of the internal carotid artery, but is due to injury of the ascending pharyngeal artery (p. 621) or one of the palatine arteries.

The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid muscle.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the oesophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as retro-pharyngeal abscess. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuration of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by gumma or by acute pharyngitis. In these cases the pus may be easily evacuated by an incision, with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy; the abscess can be felt bulging at the side of the neck and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sterno-mastoid and the deep fascia should be divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of sinus forceps are now inserted along the director and the opening into the cavity dilated.

Foreign bodies not infrequently become lodged in the pharynx and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the oesophagus is about six inches.

Hypertrophy of the adenoid tissue of the naso-pharynx produces groups of hypertrophic masses known as adenoids. A child with adenoids has a cough, and when awake or asleep, breathes noisily and with the mouth open. The voice is muffled, the hearing is impaired, the expression is vacant, the mind is dull, and the tonsils are enlarged.

THE OESOPHAGUS (Figs. 826, 827, 828, 829).

The oesophagus (οίῳ, οἶα, I carry; κατεῖλ, to eat) or gullet is a muscular canal, averaging about nine or ten inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae descends, along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates in the stomach wall at the point known as the cardia opposite the tenth dorsal vertebra or possibly opposite the intervertebral disk between the tenth and eleventh dorsal vertebrae. The general direction of the oesophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to
the oesophageal opening of the Diaphragm (*hiatus oesophageus*). The oesophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

The diameter of the largest portion of the oesophagus where it is contracted is about half an inch; when it is fully dilated, an inch or even more.

In the neck the oesophagus, when at rest, is flattened, the anterior and posterior walls approaching each other. The canal in the neck is round or oval, and the lumen is stellate (Cunningham). The oesophagus is somewhat constricted at three points. One constriction is at the very beginning of the tube; another is where the left bronchus crosses it; another is at the point where the oesophagus passes through the Diaphragm. The tube at each constricted point is distinctly flattened. The diameter of each of these constricted parts is slightly under one-half inch, the diameter of the rest of the tube when contracted is one-half inch, but when dilated may reach or exceed one inch. The average distance from the upper incisor teeth to the beginning of the gullet is about six inches; the average distance from the incisor teeth to the cardiac opening of the stomach is fifteen or sixteen inches. The portion of the oesophagus which is in the neck is called the **cervical portion** (*pars cervicalis*); the portion in the thorax, the **thoracic portion** (*pars thoracalis*), and the portion which lies in the oesophageal opening of the Diaphragm, the **diaphragmatic portion**. The margin of the oesophageal orifice is narrow in front, thicker behind and to the sides. Behind and to the sides the diaphragmatic portion of the oesophagus is about half an inch in length. In front there is only a thin edge of Diaphragm in contact with the gullet. The oesophagus is connected to the margins of the diaphragmatic orifice by connective tissue. The so-called **abdominal portion of the oesophagus** (*pars abdominalis*) is not over half an inch in length, and is limited to the small portion of the anterior and left lateral surface observed when a stomach which is completely empty is drawn downward with considerable force. The abdominal portion of the oesophagus is covered with peritoneum; the corresponding portions of the right lateral and posterior walls are not covered by peritoneum. This uncovered portion of the oesophagus runs downward and to the left and lies directly

![Diagram](image)

Fig. 826.—Pleural cul-de-sac of the posterior mediastinum.
behind the oesophageal groove on the posterior surface of the left lobe of the liver, but does not actually touch the groove, which in reality holds the thick, right edge of the oesophageal opening of the Diaphragm. When the stomach is distended the abdominal portion of the gullet ceases to exist and becomes part of the stomach wall.

Relations.—In the neck the oesophagus is in relation, in front, with the trachea, and it is connected to the posterior wall of the trachea by areolar tissue. At the lower part of the neck, where it projects to the left side, it is in relation in front with the thyroid gland and thoracic duct; behind, it rests upon the vertebral column and Longi colli muscles; on each side, it is in relation with the common carotid artery (especially the left, as the gullet inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax, it is at first situated a little to the left of the median line; it then passes behind the aortic arch, being separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, in front, with the trachea, the arch of the aorta, the left common carotid and left subclavian arteries, which incline toward its left side, the left bronchus, the pericardium, and the Diaphragm; behind, it rests upon the vertebral column, the Longi colli muscles, the right intercostal arteries, and the vena azygos minor; and below, near the Diaphragm, upon the front of the aorta; laterally, it comes in contact with both pleurae, especially with the left pleura above and the right pleura below; it overlaps the vena azygos major, which lies on its right side, while the descending aorta is placed on its left side. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it, each nerve spreading out into a plexus, the oesophageal plexus, around the tube. The two plexuses are joined to each other. The right nerve forms the posterior oesophageal plexus (plexus oesophageus posterior); the left nerve the anterior oesophageal plexus (plexus oesophageus anterior).

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the oesophagus; higher up, it is placed behind it, and, crossing about the level of the fourth dorsal vertebra, is continued upward on its left side.

Above the aortic arch and the arch of the great azygos vein above the root of the right lung, the pleurae are close to but not in actual contact with the oesophagus.

Below the arch of the great azygos vein the right side of the oesophagus is covered with pleura nearly to the diaphragmatic opening. The posterior surface of the gullet also may be covered with pleura. Below the arch of the aorta on the left side the pleura covers only a small portion of the oesophagus, that is, a portion of the left wall, a little above the diaphragmatic opening.
**Anomalies.**—There may be openings of the oesophagus into the trachea. A diverticulum or pressure pouch may exist. Such a pouch is usually placed upon the posterior wall near the pharynx. There may be congenital constriction, tubular or annular.

**Structure.**—The oesophagus is fastened to adjacent structures by connective tissue called the tunica adventitia. The tube has three coats—an external or muscular, a middle or areolar, and an internal or mucous coat.

The Muscular Coat (tunica muscularis).—The muscular coat is composed of two planes of fibres of considerable thickness, an external plane of longitudinal and an internal plane of circular fibres.

---

The Longitudinal Fibres are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor of the pharynx; as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Cunningham as passing between the oesophagus and the left pleura (m. pleurooesophageus), where it covers the thoracic aorta, or between the oesophagus and the root of the left bronchus (m. bronchooesophageus), or the back of the pericardium, as well as other still more
rare accessory fibres. In Fig. 829, taken from a dissection in the Museum of the Royal College of Surgeons of England, several of these accessory slips may be seen passing from the oesophagus to the pleura, and two slips passing to the back of the trachea just above its bifurcation. These slips of muscular fibres which pass to adjacent structures give support to the oesophagus. Below, the longitudinal fibres of the oesophagus are continued into the longitudinal fibres of the stomach.

The **Circular Fibres** are continuous above with the Inferior constrictor of the pharynx; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part. Below, the circular fibres pass into the circular and oblique fibres of the stomach.

The muscular fibres in the upper part of the oesophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre. At the cardia they act as a sphincter to solid food. Some maintain that this sphincter is closed *tonically*, others that it opens and closes rhythmically during gastric digestion.

**The Submucous or Areolar Coat (tunica submucosa).**—The submucous or areolar coat connects loosely the mucous and muscular coats. It consists of dense connective tissue and contains blood-vessels, nerves, and *oesophageal glands* (*glandulae oesophageae*). The glands are mucous glands and are found throughout the length of the gullet. The ducts of the glands pass through the muscularis mucosae. These ducts are surrounded by adenoid tissue.

**The Mucous Coat (tunica mucosa).**—The mucous coat is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distention of the tube. Its surface is studded with minute papillae, and is covered throughout with a thick layer of stratified pavement epithelium. The mucous coat contains glands which differ from the mucous glands of the submucous tissue. They are branched and tubular (Hewlett) and are called the **superficial glands**. There are two chief groups of superficial glands; one near the beginning, and the other near the termination of the oesophagus. The ducts of the superficial glands are not surrounded by lymphoid tissue (Hewlett). Beneath the mucous membrane, between it and the submucous coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the *muscularis mucosae* (*lamina muscularis mucosae*). At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

**Vessels of the Oesophagus.**—The larger vessels are in the submucosa and send branches to the mucosa and muscularis. The **arteries** supplying the oesophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta and the bronchial arteries, and from the gastric branch of the celiac axis, and from the left inferior phrenic of the abdominal aorta. They have for the most part a longitudinal direction. The **veins** are gathered into a plexus on the outer surface of the oesophagus. This plexus receives the venous blood from the walls of the tube. From the lower portion of the plexus branches go to the **coronary vein of the stomach**. Higher up branches go to the *azygos veins*.
and thyroid veins. In this manner a communication is opened between the portal veins and the systemic veins.

Lymphatics of the Oesophagus.—The lymphatics drain into the inferior deep cervical glands and the glands of the posterior mediastinum.

Nerves of the Oesophagus.—The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats. From this fibres pass to supply the muscle, and others go to the submucous tissue to form a secondary plexus. It is usual to regard the plexus as consisting of two parts, an anterior oesophageal plexus, derived from the left pneumogastric, and a posterior oesophageal plexus, derived from the right pneumogastric. These two plexuses are in the posterior mediastinum; they communicate with each other and contain sympathetic fibres.

Movements and Innervation of the Oesophagus.

Movements.—When liquid is swallowed it is, as pointed out by Kronecker and Meltzer, suddenly forced into the gullet by the contraction of the Mylo-hyoid muscle, the tube playing a practically passive part.1 In the passage of solid and semisolid food the oesophagus contracts. It does not contract, as was once thought, in sections, but there is a peristaltic wave. The wave at a given point lasts in the neck region about 3.5 seconds, and from five to nine seconds in the thoracic region.2 The lower end of the oesophagus or cardia has a sphincter, the cardiac sphincter. It is usually taught that this sphincter is tonically contracted. When a mouthful of food is swallowed it rests above the sphincter for a moment and is then forced through by muscular contractions (Kronecker and Meltzer). If several acts of swallowing follow each other rapidly the sphincter relaxes so that there is no resistance to the passage of food. In cats Dr. Walter B. Cannon3 has demonstrated "rhythmical relaxations of the cardia, so that fluid food streams from the stomach into the oesophagus even above the level of the heart, then is pressed into the stomach again by a peristaltic wave, only to be released a moment later to pour into the oesophagus anew."

Innervation.—There is in the oesophagus a local reflex, but peristalsis is dominated by the central nervous system. "It seems probable that the peristaltic contractions of the oesophagus, to be efficient, must be supported by nervous influences from outside. In this respect the oesophagus is different from the remainder of the alimentary canal."4

Surgical Anatomy.—The relations of the oesophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of stricture of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the oesophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the oesophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that obstruction of the oesophagus, and consequent symptoms of stricture, are occasionally produced by aneurism of some part of the aorta pressing upon the tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently downward, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the oesophagus and can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, and the body is lodged above the lower one-third of the gullet, external oesophagotomy is performed. If the foreign body is lodged in the lower one-third of the gullet the stomach is opened (gastrotomy) and the foreign body is extracted. If the foreign body is allowed to remain lodged in the oesophagus, extensive inflammation and ulceration may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of oesophagotomy is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length,

THE ABDOMEN

should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin, Platysma, and deep fascia. The edges of the wound being separated, the Omo-hyoid muscle should, if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, must be drawn outward, and retained in that position by retractor: the oesophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The oesophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new-grown or aneurism, etc.

The different forms of stricture are: (1) the spasmodic, occurring in neurotic individuals, and intermittent in character, so that the dysphagia is not constant. Spasmodic stricture of the oesophagus sometimes occurs in cases of cancer of the stomach and cancer of the liver; (2) fibrous, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epithelomatous, in its nature. Cancer is most common either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice. Cicatricial stricture may be treated by gradual dilatation. If a stricture is impassible from above, the stomach may be opened, an instrument passed from below, and a string used to divide the stricture.

The operation of oesophagostomy has occasionally been performed in cases where the stricture in the oesophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference is undertaken, with the idea of forming a mouth to introduce food, to perform gastrostomy. The operation of oesophagostomy is performed in the same manner as oesophagotomy, but the edges of the opening in the oesophagus are stitched to the skin incision. Gastrostomy is the only operation to be thought of in malignant stricture.

THE ABDOMEN.

The abdomen (from abdo, I put away or hide, or possibly from adeps, fat) is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward; the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levator ani muscles. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the abdomen proper; and a lower and smaller part, the pelvis. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

The abdomen proper differs from the other great cavities of the body in being bounded for the most part by muscles and fasciae, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex (Fig. S31). In the adult male, with moderate distention of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

Boundaries.—The boundary between the thorax and abdomen is the Diaphragm. This muscle forms a dome over the abdomen, and the cavity extends high into the bony thorax, reaching to the level of the junction of the fourth costal cartilages with the sternum. The lower end of the abdomen is limited by the structures which clothe the inner surface of the bony pelvis, principally the Levatores ani and Coccygei muscles on either side. These muscles are sometimes termed the Diaphragm of the pelvis. The abdomen proper is bounded in front and at the sides by the lower ribs, the abdominal muscles, and the venter ili; behind, by the vertebral column and the Psoas and Quadratus lumborum muscles; above, by the Diaphragm; below, by the brim of the pelvis. The muscles forming the
boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named, according to the part which it covers.
The abdomen contains (Fig. 830) the greater part of the alimentary canal; some of the accessory organs to digestion—viz., the liver and pancreas, the spleen, the kidneys, and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the peritoneum (Fig. 853.)

The Apertures in the Walls of the Abdomen.—The apertures found in the walls of the abdomen, for the transmission of structures to or from it, are the umbilicus, for the transmission (in the foetus) of the umbilical vessels; the caval opening in the Diaphragm, for the transmission of the inferior vena cava; the aortic opening, for the passage of the aorta, vena azygos major, and thoracic duct; and the oesophageal opening, for the oesophagus and pneumogastric nerves. Below, there are two apertures on each side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

![Fig. 831.—Schematic outlines of the abdomen.](image)

Regions (Fig. 832).—For convenience of description of the viscerae, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn around the body, the one through the extremities of the ninth ribs where they join their costal cartilages, and the other through the highest points of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle, and a lower. If two parallel lines are drawn perpendicularly upward from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.¹

The middle region of the upper zone is called the epigastric (ἐπι, over; γαστῆρ, the stomach); and the two lateral regions, the right and left hypochondriac (ὑπός, under; γαστῆρ, the cartilages). The central region of the middle zone is the mesogastric or umbilical; and the two lateral regions, the right and left lumbar. The middle region of the lower zone is the hypogastric or pubic region; and the lateral regions are the right and left inguinal or iliac. The viscerae contained in these different regions are the following (Fig. 832):

¹ Anatomists are far from agreed as to the best method of subdividing the abdominal cavity. Cunningham suggests that the lower line should encircle the body on a level with the highest point of the iliac crest, as seen from the front—a point corresponding with a prominent tubercle on the outer lip of the iliac crest about two inches behind the anterior superior spine. Addison (Journal of Anatomy and Physiology, vols. xxxiv, and xxxv.), in a careful analysis of the abdominal viscerae in forty subjects, adopts the following lines: (1) a median, from the symphysis pubis to the ensiform cartilage; (2) two lateral lines drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line half-way between the symphysis pubis and the suprasternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis.—Ed. of 15th English edition.

Jüessel draws a line through the cartilaginous ends of the tenth ribs; a line through the two anterior superior spines of the ilia. On each side he carries a perpendicular line from the iliopectineal eminence to the horizontal line connecting the tenth ribs. By this plan the highest plane is subcostal.
Right Hypochondriac.

The greater part of the right lobe of the liver, the hepatic flexure of the colon, and part of the right kidney.

Epigastric Region.

The greater part of the stomach, including both cardiac and pyloric orifices, the left lobe and part of the right lobe of the liver and the gall-bladder, the pancreas, the duodenum, the suprarenal capsules, and parts of the kidneys.

Left Hypochondriac.

The fundus of the stomach, the spleen, the extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.

Right Lumbar.

Ascending colon, part of the right kidney, and some convolutions of the small intestines.

Umbilical Region.

The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.

Left Lumbar.

Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.

Right Inguinal or Iliac.

The caecum and vermiform appendix and a portion of the ascending colon.

Hypogastric Region.

Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.

Left Inguinal or Iliac.

Sigmoid flexure of the colon and a portion of the descending colon.

If the anterior abdominal wall is reflected in the form of four triangular flaps by means of vertical and transverse incisions—the former from the ensiform cartilage to the symphysis pubis, the latter from flank to flank at the level of the umbilicus—the abdominal or peritoneal cavity is freely opened into and the contained viscera are in part exposed. 1

Above and to the right side is the liver, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line, and reaching for some distance below the level of the ensiform cartilage. Below and to the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the great omentum, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera (Fig. 861). Below it, however, some of the coils of the small intestine can generally be seen, while in the right and left iliac regions respectively the caecum and the sigmoid flexure of the colon are exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or duodenum, the point of continuity being marked by a thickened ring which indicates the position of the pyloric valve. The duodenum passes toward the under surface of the liver, and then, curving downward, is lost to sight. If, however, the great omentum be thrown upward

1 It must be borne in mind that, although the term abdominal cavity is used, there is, under normal conditions, only a potential cavity or lymph-space, since the viscera are everywhere in contact with the parietes.—Ed. of 15th English edition.
over the chest, the terminal part of the duodenum will be observed passing across the spine toward the left side, where it becomes continuous with the coils of the small intestine. These measure some twenty feet in length, and if followed downward will be seen to end in the right iliac fossa by opening into the caecum, the commencement of the large intestine. From the caecum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the ascending, transverse, and descending parts of the colon. In the left iliac region it makes still another bend, the sigmoid flexure, and then follows the curve of the sacrum as far as the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side.

The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined and the latter more or less completely covered by a serous membrane, the peritoneum.

**Development of the Alimentary Canal, Viscera and Peritoneum.**—When the paraxial mesoblast of the embryo has developed a series of transverse segmentations it becomes converted into a row of dark, square segments known as the protovertebrae or the mesoblastic somites, which are separated by clear, transverse intervals. They appear first in the region that is to become the neck, and from there extend back along the entire length of the trunk. These bodies are not solely the representatives of the future permanent vertebrae, but differentiate partly into muscles and true skin.

On each side of the protovertebrae the lateral mesoblast splits into two layers.
The upper layer is applied to the epiblast, and forms with it the somatopleure or body-wall. The lower layer becomes adherent to the hypoblast, and forms the splanchnopleure or wall of the alimentary canal. The space between these two layers is the caelum or the pleuroperitoneal cavity. This body-cavity is of large size in the early stages of the development of the embryo.

Anteriorly—or, if the body is in the erect posture, superiorly—there is developed a comparatively large space called the pericardiothoracic cavity; and a transverse fold develops, which marks off this cavity from the future abdominal cavity. This fold, with many veins of large size, develops into the primary Diaphragm, although its dorsal part remains incomplete. The dorsal part is completed at a later period, constituting the Diaphragm as we see it in the adult. As Dr. Frederick J. Brockway expresses it: “The Diaphragm is thus made up of a ventral, younger part, and a dorsal, older part. When this posterior part fails to develop, there is opportunity for a congenital diaphragmatic hernia to be present.”

The pericardiothoracic cavity becomes divided into three cavities, and the two lateral ones are for a time continuous with the abdominal cavity. This continuation is, however, but temporary, and they are afterward separated. In this manner, four large serous sacs are formed. The two lateral thoracic sacs are known as the pleural sacs, and are lined with the pleura; the median thoracic sac is the pericardial sac, and is lined with the pericardium; and the abdominal sac forms the abdominal cavity, and is lined with the peritoneum.

The primitive alimentary canal, which was formed early by the closure within the embryo of a portion of the blastodermic vesicle, consists of three parts: first, the fore-gut, within the cephalic flexure, dorsal to the heart; second, the mid-gut, opening freely into the yolk-sac; and third, the hind-gut, within the caudal flexure. In the fore-gut are developed the back portion of the mouth, the tongue, the pharynx, the oesophagus, the stomach, the larger part of the duodenum, and the organs that have grown out from these structures. The hind-gut forms a portion of the colon and the rectum, with the exception of the latter’s anal end; and the mid-gut gives rise to the remainder of the digestive tube.

Development of the Alimentary Canal.—The fore-gut and hind-gut end blindly, there being at first neither mouth nor anus (Figs. 833 and 834). The upper part of the fore-gut becomes dilated to form the pharynx, in relation to which the branchial arches are developed (Fig. 836); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the oesophagus. Soon a fusiform dilatation, the future stomach, makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (Figs. 836 and 837).

This opening is at first wide, but, as the body-walls close in around the umbilicus, it is gradually narrowed into a tubular stalk, the yolk-stalk or vitello-intestinal duct.
At this stage, therefore, the alimentary canal forms a nearly straight tube in front of the notochord and primitive aorta (Fig. 834). From the stomach to the rectum it is attached to the notochord by a band of mesoblast, from which the common mesentery of the gut is subsequently developed. The stomach undergoes a further dilatation, and its two curvatures can be recognized (Figs. 838 and 841), the greater directed toward the vertebral column and the lesser toward the anterior wall of the abdomen, while of its two surfaces one looks to the right and the other to the left. The mid-gut also undergoes great elongation, and forms a V-shaped loop which projects downward and forward; from the bend or angle of the loop the vitello-intestinal duct passes to the umbilicus (Fig. 841). For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month this is withdrawn. With the lengthening of the tube, the mesoblast, which attaches it to the future vertebral column and which carries the blood-vessels for the supply of the gut, is thinned and drawn out to form the primitive or common mesentery. The portion of this mesentery which is attached to the greater curvature of the stomach is named the mesogastrium, and the parts which suspend
the colon and rectum are respectively termed the mesocolon and mesorectum (Fig. 841). About the sixth week a lateral diverticulum makes its appearance a short distance beyond the vitello-intestinal duct, and indicates the future caecum or boundary between the small and the large intestine. This caecal diverticulum has at first a uniform calibre, but its blind extremity remains rudimentary and forms the vermiform appendix (Figs. 841 and 842). Changes also take place in the position and direction of the stomach. It falls over on to its right surface, which henceforth is directed backward, while its original left surface looks forward; further, its greater curvature is drawn downward and to the left, away from the vertebral column, while its lesser curvature is directed upward, and the commencement of the duodenum is pushed over to the right side of the middle line. The mesogastrium, being attached to the greater curvature, must necessarily follow its movements, and hence it becomes greatly elongated and drawn outward from the vertebral column, and, like the stomach, what was originally its right surface is now directed backward and its left forward. In this way a pouch, the bursa omentalis, is formed behind the stomach; this pouch is the future lesser sac of the peritoneum, and it increases in size as the alimentary tube undergoes further development; the entrance to the pouch constitutes the future foramen of Winslow (Figs. 838, 842, and 845). The remainder of the mid-gut becomes greatly increased in length, so that the tube is coiled on itself, and this increase in length demands a corresponding increase in the width of the intestinal attachment of the mesentery, so that it becomes plaited or folded.

At this stage the small and the large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.\(^1\)

\(^1\) Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (rami intestini tenuis) also arise from the right instead of the left side of the superior mesenteric artery.

---

Fig. 836.—Human embryo, about fifteen days old. Brain and heart represented from right side; alimentary canal and yolk-sac in mesial section. (After His.)
The gut now becomes rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the caecum is placed immediately below the liver; about the sixth month the caecum descends into the right iliac fossa, and the large intestine now forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front
of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (Fig. 842). Sometimes the downward progress of the caecum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downward to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior wall of the bursa omentalis, but ultimately

the two blend, and hence the great omentum appears as if attached to the transverse colon (Figs. 845, 846, and 847). The mesentery of the duodenum, in which
the rudiment of the pancreas is enclosed, disappears, and so this part of the gut becomes fixed to the posterior abdominal wall, and the pancreas lies entirely behind the peritoneal membrane. The mesenteries of the ascending and descend-

![Diagram showing abdominal parts](image)

**Fig. 841.**—Abdominal part of alimentary canal and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.) (From Kollmann's Entwickelungsgeschichte.)

The small omentum is formed by a thinning of the mesoblast or anterior primitive mesentery, which attaches the lesser curvature of the stomach to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoblast is divided into two parts—viz., the small omentum between the stomach and liver, and the falciform ligament between the liver and the abdominal wall and Diaphragm (Fig. 844).
The anus is developed as a slight invagination of the epiblast a short distance in front of the posterior end of the hind-gut. This invagination is termed the *proctodaeum*, the mesoblast between it and the hypoblastic lining of the hind-gut is thinned, and ultimately the septum breaks down and disappears, and the hind-gut opens on the surface; into this part of the hind-gut the urinary and generative organs open for a time, and so constitutes a *common cloaca*. The small portion of the hind-gut behind the orifice of the anus is named the *caudal* or post-anal gut; it communicates with the neural tube by means of a canal, the *neurenteric canal*, already referred to. Ultimately the post-anal gut becomes obliterated, and it, together with the neurenteric canal, finally disappears.

The *peritoneal cavity* is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is developed from these layers.

The *tongue* originates from the floor of the pharynx. The anterior or papillary portion first appears as a rounded elevation, the *tuberculum impar*, between the ventral ends of the mandibular and hyoid arches (Fig. 848). Between the third and fourth arches a second larger elevation arises, in the centre of which is a median groove or furrow. This second elevation is termed the *furcula*, and from it the epiglottis is developed, while the median furrow becomes the entrance to the larynx (Fig. 849). The tuberculum impar and the furcula are at first in apposition, but are soon separated by a ridge produced by the forward growth of the second and third arches. This ridge gives rise to the posterior part of the tongue and extends forward in the form of a V, so as to embrace between its two limbs the tuberculum impar. At the apex of the V there is a pit-like invagination to form the middle thyroid rudiment, and this depression persists as the foramen caecum of the adult. The union of the two parts of the tongue is indicated even in the adult by a V-shaped depression, the apex of which is at the

foramen caecum, while the two limbs run outward and forward parallel to but a little behind the circumvallate papillae, which are therefore developed from
The tuberculum impar (Figs. 848, 849, and 850). The tonsils are developed from the second branchial cleft, and make their appearance between the fourth and fifth months.

The liver arises in the form of two diverticula or hollow outgrowths from the ventral surface of that portion of the fore-gut which afterward becomes the duodenum (Figs. 836 and 837). The outgrowths, which represent the right and the left lobes, respectively, of the adult liver, give off solid buds of cells, which grow into columns or cylinders; these unite with one another in every direction to form a close network, in the meshes of which are contained the capillary blood-vessels. Some of these columns become hollowed out and form the bile-ducts, while the remainder constitute the secreting structure. The minute ducts thus produced unite to form the right and left hepatic ducts; while the common bile-duct is developed as a protrusion from the duodenal wall, and as it grows the liver becomes shifted away from the duodenum. The gall-bladder and cystic duct are formed by
a hollow evagination from the wall of the common bile-duct. About the third month the liver almost fills the abdominal cavity. From this period the relative development of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but up to the end of fetal life the liver remains relatively larger than in the adult.

The pancreas is also an early formation, being far advanced in the second month. It originates as a hollow projection from the hypoblast of the dorsal wall of the duodenum (Figs. 837 and 838), opposite the hepatic diverticula, which, as we have already seen, spring from its ventral wall. This hollow process grows between the two layers of the dorsal mesentery and sends out offshoots, which
branch abundantly and form a complicated tubular gland. As torsion of the stomach takes place, the pancreas assumes a transverse position and becomes fixed across the dorsal wall of the abdomen, the posterior layer of its mesentery undergoing absorption. Its duct ultimately opens into the duodenum together with the common bile-duct.

The spleen, on the other hand, is of mesoblastic origin, for there is never any connection between the intestinal cavity and the substance of this organ. It originates in the mesenteric fold which connects the stomach to the vertebral column (mesogastrium) (Fig. 841).

**THE PERITONEUM (TUNICA SEROSA).**

During life and in the uncut corpse the peritoneal cavity (cavum peritonaei) is air-tight. It is not a real cavity, as muscular tension and atmospheric pressure permit no vacant space to form. When the surgeon or anatomist opens the abdomen, the peritoneal cavity is at that moment produced.

The peritoneum (from περί, about, and τενω, I stretch) is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained visceræ. In the female the peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The portion of the peritoneum applied against the abdominal parietes constitutes the parieta! peritoneum; the portion reflected over the visceræ, the visceral peritoneum. The free surface of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small cavity of serous fluid. Hence the visceræ can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. Its attached surface is rough, being connected to the visceræ and inner surface of the parietes by means of areolar tissue termed the subserous areolar tissue (tela subserosa). The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and also in the middle line of the abdomen.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement—an arrangement which can only be clearly understood by following the changes which take place in the alimentary canal during its development; and therefore the student is advised to pref ace his study of the peritoneum by reviewing the remarks on Embryology.

**Structure of the Peritoneum.—**It is a thin, glistening serous membrane and consists of a connective-tissue layer and one layer of flat endothelial cells upon the free surface of the membrane. The connective-tissue layer consists of bundles of connective tissue which contain many connective-tissue cells and elastic fibres. It contains a multitude of lymph-spaces, lymph-vessels, and lymph-capillaries.
Beneath the peritoneum is a layer of lax and spongy connective tissue which serves to bind the serous membrane to parts beneath. This layer is called the subserous connective tissue. In some regions it is plentiful; in others, as over the liver and intestine, it is very scantily developed. The endothelial cells are flat and polygonal. Some hold that they are joined together by cement-substance. Byron Robinson asserts that there is no cement-substance, but rather an organized connection between the protoplasmic processes of adjacent cells.

On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these, the stomata, are surrounded by a ring of cubical endothelium (Fig. 851), and communicate with lymphatic capillaries; others, the stigmata or pseudostomata, are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue. Stomata are particularly numerous in the region of the Diaphragm and are relatively scanty in the region of the pelvis.

The amount of fluid contained in the closed sac is, in most cases, only sufficient to moisten the surface, but not to furnish any appreciable quantity of liquid. When a small quantity can be collected, it is found to resemble lymph, and, like that fluid, coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a more watery fluid, but still contains a considerable amount of proteid which is coagulated on boiling.

The peritoneum is a lymph-sac and its walls contain a great quantity of lymphatic structures. In the subserous tissue the numerous lymph-spaces obtain fluid from the peritoneal cavity by way of the stomata of the endothelial coat, and from these lymph-spaces lymph-vessels take origin. Byron Robinson points out that the lymphatic system of the peritoneum consists of: 1. Interstitial lymph-spaces. 2. Non-valved capillaries. 3. Valved lymphatic channels. The subendothelial interstitial lymph-spaces intercommunicate and can take up an immense quantity of fluid from the peritoneal cavity. Normally the spaces contain both nutrient material and waste products. Through these spaces blood capillaries pass, and from these spaces lymph-capillaries come. Lymphatics are particularly plentiful in—1, the tendinous portion of the Diaphragm; 2, the ligamenta lata; 3, the omentum; 4, the ventral surface of the small intestine; 5, the liver and spleen. 1

The lymph from this region reaches the mediastinal or diaphragmatic glands. The serous surface of the Diaphragm is the region chiefly efficient in absorption from the peritoneum, and there is a current in the peritoneal cavity directed toward the Diaphragm. 2 Absorption is very rapid from the peritoneal cavity. Fluid equalling from 3 to 8 per cent. of the body-weight can be absorbed in one hour. There are a multitude of nerves in the peritoneum, and it seems probable that each endothelial

---

1 The Peritoneum. By Byron Robinson.
2 Ibid.
cell receives a nerve ending. The minute arteries of the peritoneum are surrounded by nerve-plexuses. According to Byron Robinson, the nerves of the peritoneum are: 1. Medullated. 2. Non-medullated. 3. Fibres of Remak. 4. The Vater-Pacini corpuscles and other varieties of nerve endings. 5. Nerve-cells. The visceral peritoneum contains many more nerves than the parietal peritoneum.

The parietal peritoneum (peritonaeum parietale) lines the wall of the abdominal cavity. The visceral peritoneum (peritonaeum viscerale) covers the visera. Back of the parietal peritoneum is a space, the retro-peritoneal space (spatium retro-peritonaeale), which contains the great vessels and nerves, the suprarenal capsules, the kidney, and ureters (Figs. 853, 854, 855, 856, and 857).

We describe the peritoneum as consisting of two sacs, a greater sac and a lesser sac (Fig. 853). The larger part of the abdominal cavity is lined by the greater sac, as most of the visera are covered by it. The lesser sac is placed largely behind the stomach. These two sacs are not two distinct cavities which communicate. They constitute one cavity, a portion of which has been formed into a diverticulum or recess by a process of constriction, the result of changes produced in the position of adjacent visera by development. Prof. Birmingham says: "If the great sac be compared to a bag, the lesser sac might be represented as a pocket lying behind, and opening into it by a narrow orifice, the foramen of Winslow, on its posterior wall." The greater sac lines the walls of the abdominal cavity and covers the visera which are invested by peritoneum, except the posterior portion of the stomach, the suprarenal capsule of the left side, the superior surface of the pancreas, the Spigelian lobe and the caudate lobes of the liver, and portions of the spleen, left kidney, and transverse colon, which are covered by peritoneum of the lesser sac.

To trace the continuity of the membrane from one viscus to another, and from the visera to the parietes, it is necessary to follow its reflections in the vertical and horizontal directions, and in doing so it matters little where a start is made.

If the stomach is drawn downward, a fold of peritoneum will be seen stretching from its lesser curvature to the transverse fissure of the liver (Figs. 853 and 859). This is the gastro-hepatic or lesser omentum (omentum minus), and consists of two layers; these, on being traced downward, split to envelop the stomach, covering respectively its anterior and posterior surfaces. At the greater curvature of the stomach they again come into contact and are continued downward in front of the transverse colon, forming the anterior two layers of the great or gastro-colic omentum (omentum majus) (Figs. 853 and 861). Reaching the free edge of this fold they are reflected upward as its two posterior layers, and thus the great omentum consists of four layers of peritoneum. Followed upward the two posterior layers separate so as to enclose the transverse colon, above which they once more come into contact and pass backward to the abdominal wall as the transverse mesocolon (mesocolon transversum) (Fig. 853). Reaching the abdominal wall about the level of the transverse part of the duodenum, the two layers of the transverse mesocolon become separated from each other and take different directions; the upper or anterior layer, known as the ascending layer of the transverse mesocolon, ascends in front of the pancreas, and its further course will be followed presently (Fig. 853). The lower or posterior layer is carried downward, as the anterior layer of the mesentery, by the superior mesenteric vessels to the small intestine, around which it may be followed and subsequently traced upward as the posterior layer of the mesentery to the abdominal wall. From the posterior abdominal wall it sweeps downward over the aorta into the pelvis, where it invests the first part of the rectum and attaches it to the front of the sacrum by a fold termed the mesorectum (Fig. 863, p. 1259). Leaving first the sides and then the front of the second part of the rectum it is reflected on to the back of the bladder, and, after covering the posterior and

3 "Ibid."
upper aspects of this viscus, is carried by the urachus and obliterated hypogastric arteries as folds, on to the posterior surface of the anterior abdominal wall (Fig. 852). The fold upon the urachus is the plica urachi (plica umbilicalis media); the fold on each obliterated hypogastric artery is the plica hypogastrica (plica umbilicalis lateralis). Between the rectum and bladder it forms a pouch, the recto-vesical pouch (excavatio rectovesicalis), bounded on the sides by two crescentic or semilunar folds (plicae rectovesicales), which pass from the posterior surface of the bladder to the sides of the rectum; the bottom of this pouch is about on a level with the middle of the vesiculae seminales—i. e., three inches or so from the orifice of the anus. When the bladder is distended the peritoneum is carried up with the expanded viscus, so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of the peritoneal membrane. When the bladder is empty the peritoneum forms a transverse fold over its upper surface (plica vesicalis transversa).

In the female the peritoneum is reflected from the rectum on to the upper part of the posterior vaginal wall, forming the recto-vaginal pouch or pouch of Douglas (excavatio rectouterina) (Fig. 853). In the pouch of Douglas are two folds of peritoneum (plica rectouterinae), which begin at the posterior surface of the cervix, extend back to the sides of the rectum, and bound above the deepest portion of the pouch. The pouch is then carried over the posterior aspect and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, forming here a second but shallower depression, the utero-vesical pouch (excavatio vesicouterina). It is also reflected from the sides of the uterus to the lateral wall of the pelvis on each side as an expanded fold, the broad ligament of the uterus (ligamentum latum uteri), in the free margin of each broad ligament can be felt a thickened cord-like structure, the Fallopian tube (tuba uterina [Fallopii]).

When the peritoneum lining the anterior abdominal wall is examined from behind, it is noticed that certain structures which lie in front of it form five peritoneal ridges (Fig. 852). The structure in the middle line is the urachus, which is the remains of the foetal allantoid. In the adult it is a fibrous cord which passes from the umbilicus to the summit of the bladder. This cord is slender above, but broader below. External to the urachus are the fibrous cords which resulted from obliteration of the hypogastric arteries (arteriae umbilicales). These cords become more slender as they ascend toward the sides of the urachus and pass to the umbilicus. More external still are the folds formed by the deep epigastric arteries. The fold over each epigastric artery is the plica epigastrica; the fold over each obliterated hypogastric artery is the plica umbilicalis lateralis; the fold over the obliterated urachus is the plica umbilicalis media.

The five peritoneal ridges formed by the above-named structures create three peritoneal fossae on each side, called the inguinal fossae or pouches (fovea inguinales). The external inguinal fossa (fovea inguinalis lateralis) is external to the deep epigastric artery and corresponds to the internal abdominal ring. There is a funnel-shaped depression in its floor marking the point at which the inguinal process passed down. This depression, if marked, predisposes to oblique inguinal hernia. The middle inguinal fossa (fovea inguinalis mediialis) is placed between the deep epigastric arteries and the obliterated hypogastric vessels. The internal inguinal fossa or the supravesical fossa (fovea supravesicalis) is between the obliterated hypogastric artery and the urachus. Just beneath the inner termination of Poupart's ligament there is another fossa, the femoral or crural fossa (fovea femoralis), which corresponds to the situation of the femoral ring. The obliterated hypogastric artery is to the inner side of this fossa.

On following the parietal peritoneum upward on the back of the anterior abdominal wall it is seen to be reflected around a fibrous band, the ligamentum teres or obliterated umbilical vein (Figs. 855, 856, and 857), which reaches from the
umbilicus to the under surface of the liver. Here the membrane forms a somewhat triangular fold, the falciform or suspensory ligament of the liver (ligamentum falciforme hepatis), which attaches the upper and anterior surfaces of that organ to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the under surface of the anterior part of the Diaphragm and is reflected from it on to the upper surface of the liver as the anterior or superior layer of the coronary ligament (ligamentum coronarium hepatis anterior). Covering the upper and anterior surfaces of the liver it is reflected around its sharp margin on to its under surface as far as the transverse fissure, where it is continuous with the anterior layer of the small omentum from which a start was made (Fig. 853). The posterior layer of this omentum is carried backward from the transverse fissure over the under surface and Spigelian lobe of the liver, and is then reflected, as the posterior or inferior layer of the coronary ligament (ligamentum coronarium hepatis posterior), on to the Diaphragm and is prolonged downward over the pancreas to become continuous with the ascending layer of the transverse mesocolon (Fig. 853). Between the two layers of the coronary ligament there is a triangular surface of the liver which is devoid of peritoneum; it is named the bare area of the liver, and is attached to the Diaphragm by connective tissue. If, however, the two layers of the
coronary ligaments are traced toward the right and left margins of the liver, they approach each other, and, ultimately fusing, they form the right and left lateral ligaments of the liver and attach its right and left lobes respectively to the Diaphragm.

If the small omentum is followed toward the right side it is seen to form a distinct free edge around which its anterior and posterior layers are continuous with each other and between which are situated the portal vein, hepatic artery, and bile-duct. If the finger is introduced behind this free edge, it passes through a somewhat constricted ring, the foramen of Winslow (foramen epiploicum [Winslow]) (Figs. 853, 855, and 858). This is the communication between what are termed the greater and lesser sacs of the peritoneum and has the following boundaries: in front, the free edge of the gastro-hepatic omentum. This free edge is called the ligamentum hepatoduodenale. The gastro-hepatic omentum has the portal vein, hepatic artery, and bile-duct between its two layers (Fig. 859); behind the foramen of Winslow is the vena cava inferior; above, are the Spigelian and caudate lobes of the liver; below, the duodenum and the hepatic artery, as the latter passes forward and upward from the cœliac axis.

The lesser peritoneal cavity or the lesser sac of the peritoneum (bursa omentalis) (Figs. 853, 855, and 858), therefore, lies behind the small omentum and has the following dimensions: above, it is limited by the portion of the liver which lies behind the transverse fissure; below, it extends downward into the great omentum, reaching, in the foetus, as far as its free edge (Fig. 846); in the adult, however, its vertical extent is limited by adhesions between the layers of the omentum. In front, it is bounded by the small omentum, stomach, and anterior two layers of the great omentum; behind, by the two posterior layers of the great omentum, the transverse colon, and ascending layer of the transverse mesocolon which passes upward in front of the pancreas as far as the posterior surface of the liver. Laterally the lesser sac reaches from the foramen of Winslow on the right side as far as the spleen on the left (recessus lienalis) (Fig. 860), where it is limited by the lienorenal ligament. The extent of the lesser sac and its relations to surrounding parts can be definitely made out by tearing through the small omentum and inserting the hand through the opening thus made. A passage (vestibulum bursae omentalis) leads out from the foramen of Winslow over the head of the pancreas to the left as far as the median vascular gastro-pancreatic fold (plica gastropancreatica) (Fig. 858). This fold carries the gastric artery and the coronary vein. From the vestibule there is a narrow and upward prolongation behind the lesser omentum and caudate lobe of the liver and in front of the lumbar portion of the Diaphragm. This prolongation is the superior omental recess (recessus superior omentalis). The chief part of the lesser peritoneal cavity extends downward from the gastro-pancreatic fold and is called the inferior omental recess (recessus omentalis inferior). The constriction which separates the two recesses is due to the passage around the lesser sac and to the front of the gastric and hepatic arteries. "The former winds around its left side, the latter around its right, and each raises up a fold of peritoneum which projects strongly into the sac and partially divides it into two."  

A small projection of the lesser sac passes to the right side behind the beginning of the duodenum. The splenic artery in its course to the spleen lies back of the posterior layer of the lesser sac.

It should be stated that during a considerable part of foetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own—the two posterior layers of the great omentum passing, at this stage, in front of and above the colon (Fig. 849). This condition sometimes persists throughout adult life, but as a rule adhesion occurs between the mesentery of the transverse colon

1 Prof. Cunningham's Text-book of Human Anatomy.
and the posterior layer of the great omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold.

In addition to tracing the peritoneum vertically, it is necessary to trace it horizontally (Figs. 854, 855, 856, and 857). If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater sac of the peritoneum (Fig. 854). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of the two sacs.

Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, the peritoneum covers the internal surface of the abdominal wall almost as far as the anterior border of the Quadratus lumborum muscle; it encloses the caecum, and is reflected over the

---

**Fig. 853.**—Diagrammatic mesial section of the female body, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the small sac is very darkly shaded; the peritoneum on section is shown as a white line, and a white arrow is passed through the foramen of Winslow from the great into the small sac. (Cunningham.)

sides and anterior surface of the ascending colon, fixing it to the abdominal wall, from which it can be traced over the kidney to the front of the bodies of the vertebrae. It then passes along the mesenteric vessels to invest the small intestine, and back again to the spine, forming the mesentery, between the layers of which are contained the mesenteric blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, is continued along it to the middle line of the abdomen.

Above the transverse colon (Fig. 855) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen, the membrane may be traced lining its anterior wall, and sending a process back-
ward to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course to the right, it is reflected over the front of the upper part of the right kidney, across the vena cava inferior and aorta, and over the left kidney to the hilum of the spleen, forming the anterior layer of the lienorenal ligament, the posterior layer being formed by the termination of the cul-de-sac of the greater cavity.
between the kidney and spleen. From the hilum of the spleen it is reflected to the stomach, forming the posterior layer of the \textit{gastro-splenic omentum} (\textit{ligamentum gastrolienale}). It covers the posterior surface of the stomach, and from its lesser curvature it passes around the portal vein, hepatic artery, and bile-duct, and back again to the stomach, as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and

---

**Fig. 856.**—Horizontal section through the abdomen at the level of the foramen of Winslow. (Modified from Godlee.)

**Fig. 857.**—Transverse section of peritoneum.
upon reaching the cardiac extremity it passes to the hilum of the spleen, forming the anterior layer of the gastro-splenic omentum. From the hilum of the spleen it can be traced over the surface of this organ, to which it gives a serous covering; it is then reflected from the posterior border of the hilum on to the left kidney, forming the posterior layer of the lienorenal ligament.

Numerous folds, formed by the peritoneum, extend between the various organs or connect them to the parietes. These serve to hold the organs in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of these folds are called ligaments, such as the ligaments of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the mesenteries; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called omenta.

The Ligaments of the Peritoneum.—The ligaments, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The Omenta.—The omenta are: the lesser omentum, the great omentum, and the gastro-splenic omentum.

The Lesser or Gastro-hepatic Omentum (omentum minus) (Figs. 853 and 858) is the duplicature which extends between the transverse fissure of the liver and the right side of the abdominal portion of the oesophagus, the lesser curvature of the stomach, and the upper portion of the superior surface of the duodenum. The portion going to the oesophagus and stomach is called the hepato-gastric ligament (ligamentum hepatogastricum). The division of the ligament which goes to the oesophagus is strong and dense; the division which goes to the lesser curvature of the stomach is thin and relaxed. The portion of the lesser omentum which goes to the duodenum is continuous with the first-named portion. It is called the hepato-
duodenal ligament (ligamentum hepatoduodenale). The right margin of this ligament is free and concave. The hepato-colic ligament (ligamentum hepatocolicum) is not invariably present. It is a fold of the hepato-duodenal ligament and

runs from the posterior surface of the gall-bladder to the descending portion of the duodenum or possibly to the transverse colon. From the free margin of the termination of the hepato-duodenal ligament a fold often passes to the front

of the right kidney. It is known as the duodeno-renal ligament (ligamentum duodenorenale). The lesser omentum is extremely thin, and consists of two layers of peritoneum; that is, the two layers covering respectively the anterior and
posterior surfaces of the stomach. The posterior layer is part of the wall of the lesser peritoneal cavity; the anterior layer, of the greater peritoneal cavity. When the two layers reach the lesser curvature of the stomach, they join together and ascend as the double fold to the transverse fissure of the liver; to the left of this fissure the double fold is attached to the fissure of the ductus venosus as far as the Diaphragm, where the two layers separate to embrace the end of the oesophagus. At the right border the lesser omentum is free, and the two layers of which it is composed are continuous. The anterior layer, which belongs to the greater sac, turns around the hepatic vessels to become continuous with the posterior layer belonging to the lesser one. They here form a free, rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves (Fig. 859)—all these structures being enclosed in loose areolar tissue, called Glisson’s capsule. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic artery, anastomosing with it. From the left side of the greater curvature of the stomach a fold passes to the gastric surface of the spleen, covers the spleen, and passes from the renal surface of the spleen around the left kidney to the Diaphragm.1 The fold passing to the spleen is known as the gastro-splenic ligament or the gastro-splenic omentum (ligamentum gastrolienale) (Fig. 860). The portion passing to the Diaphragm is known as the splenophrenic ligament (ligamentum phrenicolienale). The gastric veins or vasa brevia pass from the left side of the greater curvature of the stomach toward the spleen in the gastro-splenic omentum.

The Great or Gastro-colic Omentum (omentum majus) (Figs. 853 and 861) is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. At the free margins the two outer layers and the two inner layers become continuous. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribiform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries. In opening the abdomen the great omentum is rarely found spread out evenly over the intestines. It often projects between intestinal coils, or is largely gathered in some one region, or is pushed in front of the stomach by distention of the colon.

The lower portion of the lesser sac of the peritoneum continues for a distance between the ascending and descending layers of the great omentum (Fig. 853). The portion of the lesser peritoneal cavity within the great omentum is more or less obliterated in the adult by adhesion between its opposing layers. At birth the omentum is very short and barely reaches the umbilicus. In adults its length varies greatly. In some individuals it is very short; in others it passes into the pelvis. Mr. Lockwood points out that in persons under forty-five years of age the omentum can rarely be pulled down below the level of the pubic spine; in older persons it generally can.

The Gastro-splenic Omentum is the fold which connects the margins of the hilum of the spleen to the cul-de-sac of the stomach, being continuous by its lower

---

border with the great omentum. It was described as the gastro-splenic ligament (Fig. 860).

The Mesenteries.—The mesenteries are: the mesentery proper, the transverse mesocolon, the sigmoid mesocolon, the mesorectum (p. 1259), and the mesentery of the vermiform appendix. In addition to these there are sometimes present an ascending and a descending mesocolon.

The Mesentery (mesenterium) (μεσόντεριον) (Figs. 853, 862, and 863), so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. It consists of a layer of connective tissue, each side of which is covered with peritoneum. In the connective tissue there are fatty masses. Its root (radix mesenterii), the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (Fig. 863). Its intestinal border is vastly broader (measures about twenty feet); and here its two layers separate so as to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about eight inches. Its upper border is continuous with the under surface of the transverse mesocolon; its lower border, with the peritoneum covering the caecum and
ascending colon. The origin of the mesentery above is just beyond the termination of the duodenum, and it terminates below in the angle formed by the junction of the ileum and the colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lymphatic vessels and mesenteric glands. These glands number from 50 to 150. Occasionally congenital mesenteric openings exist. In stout individuals the mesentery contains much fat. If there is much fat the mesentery is not translucent; if there is little fat it is translucent. It may be actually transparent above and translucent or opaque below. The thinnest part of the mesentery is above. As we descend it becomes thicker, because of the presence of fat, fibrous ligament, and muscular tissue.\(^1\)

---

respectively. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the phrenocolic ligament (ligamentum phrenicocolicum); it passes below the spleen, and serves to support this organ, and therefore it has received the second name of sustentaculum lienis.

The Transverse Mesocolon (mesocolon transversum) (Fig. 863) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending or posterior layers of the great omentum, which, after

separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The Sigmoid Mesocolon (mesocolon sigmoideum) (Fig. 863) is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa. This portion of intestine remains always freely movable.

The Mesorectum is really only the lower portion of the sigmoid mesocolon. It is the name formerly given to the narrow fold which, according to the old defini-
tion of the rectum, connects the upper part of the rectum with the front of the sacrum. It contains the superior hemorrhoidal vessels.

The **Mesoappendix** or **Mesentery of the Vermiform Appendix** (*mesenteriolum processus vermiciformis*) (Fig. 867) is a double fold of peritoneum which usually completely surrounds the vermiform appendix. It is usually described as a triangular fold, and at a glance it appears so, but Jonnesco points out that it has four borders: a *superior* or mesenteric border; a *right* or caecal; a *left* or free, and an *inferior* or appendicular. One of the borders is often extremely short. The upper surface of the mesoappendix is continuous with the lower surface of the mesentery proper and with the left or internal fold of the peritoneum covering the caecum. The lower surface of the mesoappendix is continuous with the right or external fold of peritoneum covering the caecum. As a rule, the entire appendix is covered with peritoneum; sometimes a portion of the base is uncovered, and this portion of the diverticulum is then extraperitoneal. The tip is never extraperitoneal. The mesoappendix may be attached to the entire length of the appendix, but, as a rule, the tip is free. In fact, one-third, one-half, or two-thirds may be free and occasionally the mesoappendix is a mere vestige. Between the two peritoneal layers of the mesoappendix there is connective tissue, and often fat. In the connective tissue are the **appendicular blood-vessels**, **lymph-vessels**, and **nerves**.

The **Appendices Epiploicae** are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

![Diagram](image-url)

**Fig. 864.**—Superior and inferior duodenal fossa. (Poirier and Charpy.)

**Retro-peritoneal Fossae.**—In certain parts of the abdominal cavity there are recesses of peritoneum forming *culs-de-sac* or pouches, which are of surgical interest in connection with the possibility of the occurrence of retro-peritoneal hernia. One of these, which was previously described, is the **lesser sac of the peritoneum** (Figs. 853 and 855), which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses of fossae may be divided into three groups, viz.: (1) the *duodenal fossae*; (2) *cecal fossae*; and (3) the *intersigmoid fossa*.

1. **Duodenal Folds and Fossae.**—Moynihan has described no less than nine fossae as occurring in the neighborhood of the duodenum. Three of these are fairly constant. Five of the fossae are here considered. (a) The **inferior duodenal fossa or fossa of Treitz** (Fig. 864) is the most constant of all the peritoneal fossae in this region, being present in from 70 to 75 per cent. of cases. It is situated
opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. The opening into the fossa is directed upward, and is bounded by a thin, sharp fold of peritoneum with a concave free upper margin. This fold of peritoneum is called the inferior duodenal fold (*plica duodenomesocolica*). The tip of the index finger introduced into the fossa under the fold passes some little distance up behind the ascending or fourth portion of the duodenum. One margin of the fold is attached to the ascending portion of the duodenum; another margin is attached to the parietal peritoneum. (b) The superior duodenal fossa (Fig. 864) is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases. It often coexists with the inferior one, and its orifice looks downward, in the opposite direction to the preceding fossa. It lies to the left of the ascending portion of the duodenum. It is bounded in front by the superior duodenal fold (*plica duodenojejunalis*), which is triangular and has a free semilunar base; to the right it is blended with the peritoneal covering the ascending duodenum, and to the left with the peritoneum covering the perirenal tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. Its depth is 2 cm., and it terminates in the angle formed by the left renal vein crossing the aorta. This fossa is of importance, as it is in relation with the inferior mesenteric vein; that is to say, the vein almost always corresponds to the line of union of the superior duodenal fold with the posterior parietal peritoneum. (c) The *duodeno-jejunal fossa* or mesocolic fossa (*recessus duodenojejunalis*) is formed where the duodeno-jejunal angle enters the root of the transverse mesocolon. There are two forms: (1) a single fossa and (2) a double fossa. It can be seen by pulling the jejunum downward and to the right, after the transverse colon has been pulled upward. It will appear as an almost circular opening, looking downward and to the right, and bounded by two free borders or folds of peritoneum, the *duodeno-mesocolic ligaments*. The opening admits the little finger into the fossa to the depth of from 2 to 3 cm. The fossa
is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa. (d) **Paraduodenal fossa** or the **fossa of Landzert** (*recessus duodenoejunalis*) is most distinct in the infant, and is to the left of the ascending portion of the duodenum. The fold of peritoneum to its outer side and above is produced by the inferior mesenteric vein. Its lower limit is a fold called the **mesenterico-mesocolic fold**. (e) The **retroduodenal fossa** (Fig. 865) was described in 1893 by Jonnesco. It is a peritoneal *cul-de-sac*, sometimes found behind the horizontal and ascending portions of the duodenum.

2. **Pericæcal Folds and Fossae**.—There are at least three pouches or recesses to be found in the neighborhood of the caecum, which are termed **pericæcal fossae**. (1)
and a small portion of the caecum behind. (2) The ileo-caecal, inferior ileo-caecal or ileo-appendicular fossa (recessus ileocaecalis inferior) (Fig. 867) is situated behind the angle of junction of the ileum and caecum. It is formed by a fold of peritoneum, the ileo-caecal fold (plica ileocaecalis), which Treves called the "bloodless fold." Tuffier denies its non-vascularity, and Lockwood and Rolleston state that it contains fat, muscular fibres, and arteries and veins derived from the appendicular vessels and the anterior and posterior ileo-caecal vessels. The upper border of the fold is attached to the ileum, opposite its mesenteric attachment, and the lower border, passing over the ileo-caecal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold is sometimes called the ileo-appendicular fold. Between the ileo-caecal fold and the mesentery of the vermiform appendix is the ileo-caecal fossa. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ileo-caecal fold, and behind by the upper part of the mesentery of the appendix. (3) The retro-caecal or retro-colic

![Diagram of the retro-caecal fossa](image)

Fig. 868.—The retro-caecal fossa. The ileum and caecum are drawn backward and upward. (Souligoux.)

fossae (recessus retrocaecalis) (Fig. 868) are situated behind the caecum and ascending colon. There may be no fossa present. There may be one fossa; there are usually two (external and internal retrocolic fossae); occasionally there are more than two. The fossae are brought into view by raising the caecum. According to Berry, one or other of the fossa is present in 30 per cent. of cases. Treves thinks the retrocolic fossae are extremely rare. There may be one fossa (20 per cent. of cases) or two fossae (10 per cent. of cases). If there is but one fossa it is the internal that exists three times as often as the external. The retro-colic space, if present, varies much in size and extent. In some cases it is sufficiently large to admit the index finger and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. The external retro-colic fossa is bounded and formed by two folds: one, the external parieto-colic fold or the superior caecal fold, which is the outer layer of the ascending mesocolon, and is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the posteror-

1 The Caecal Folds and Fossae. By Richard J. A. Berry.

2 Ibid.
external aspect of the colon; and the other, the internal parieto-colic or inferior cecal fold, which is the inner layer of the ascending mesocolon. The internal retrocolic fossa is bounded externally by the internal parieto-colic fold, and is bounded internally by the mesenterico-parietal fold, which is the insertion of the mesentery into the iliac fossa.

3. The Intersigmoid Fossa (recessus intersigmoideus).—The intersigmoid fossa is constant in the foetus and common during infancy, but disappears in a large percentage of cases as age advances. Upon drawing the sigmoid flexure upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoidea, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. This fossa is produced by the incomplete fusion in the foetus of the descending mesocolon with the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Any of these fossae may be the site of a retro-peritoneal hernia. The pericecal fossae are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.

Surgical Anatomy.—Study of the lymphatics of the peritoneum by Byron Robinson and others shows that absorption takes place most rapidly from the region of the Diaphragm, less rapidly but still very actively from the region of the small intestine, slowly from the pelvic region. Clinically we know that pelvic peritonitis is not nearly so dangerous as peritonitis in the small intestine or Diaphragm areas, and that peritonitis in the region of the Diaphragm is the most fatal form of the infection. After abdominal operations in infected cases, it is well to elevate the head of the bed (Fowler's position), so as to obtain the aid of gravity in draining septic fluids away from the dangerous region and toward the safer region. In areas in which absorption is rapid, protective exudation is not apt to form. In areas in which absorption is slow, inflammatory exudation is apt to circumscribe the area and prevent diffusion. After an operation in a non-infected case, if salt solution has been left in the abdominal cavity because of shock or hemorrhage, raising the foot of the bed will aid rapid absorption of the fluid by favoring the natural current toward the Diaphragm and hurrying the fluid to a region in which absorption is rapid.

The great omentum stores up fat, and, being movable, it is able to pass to different parts of the peritoneal cavity. Dr. Byron Robinson, in his work on the Peritoneum, describes its functions as follows: "The omentum is the great protector against peritoneal infectious invasions. It builds barriers of exudates to check infection. It is like a man-of-war, ready at a moment's notice to move to invaded parts. It circumscribes abscesses; it repairs visceral wounds, and prevents adhesions of mobile viscera to the anterior abdominal wall. It resists infectious invasions by typical peritoneal exudates, and not by succumbing to absorbed sepsis. It is a director of peritoneal fluids, a peritoneal drain."

In abdominal wounds the omentum often protrudes: This structure frequently constitutes or is part of a hernia, and is almost invariably present in umbilical hernia. As a result of inflammation, it may become adherent to adjacent structures. Adhesions may be of service by matting together the intestines and circumscribing infections. They may be harmful by constricting the bowels and producing obstruction. A portion of the omentum may become adherent to some other part and form a band, and under this band the gut may be caught and strangulated. Omentum may adhere to and plug a perforation in a hollow viscus, and the surgeon may utilize it for the same purpose, or to cover a raw surface or overlie a suture line. The omentum may be in the surgeon's way while operating. If it is, the patient is placed in the Trendelenburg position (pelvis elevated).

Any tear or opening found by the surgeon in the great omentum must be closed with sutures, because of the danger that intestine might enter and be caught in such an opening. A tumor cut off from its proper blood-supply, for instance, an ovarian cyst with a twisted pedicle, may continue to receive nourishment from adherent omentum, and gangrene may thus be prevented.

1 On the anatomy of these fossae, see the Arris and Gale Lectures by Moylanhan, 1899.
2 George R. Fowler, in Medical Record, April 14, 1900.
The lax character and shifting tendency of the subserous tissue explains the occurrence of ptosis of the abdominal viscera and kidneys.

The vast number of nerves in the peritoneum accounts for the profound shock which follows a wound, attends an intraperitoneal calamity, or which develops from infection. An infective process of any portion of the peritoneum produces pain and reflex symptoms (vomiting, abdominal rigidity, intestinal paresis, etc.).

The parietal peritoneum is very sensitive to pain, but not to touch; hence, after injecting a local anesthetic and opening the abdomen, a fairly satisfactory exploration can be made with the finger.

The intestine, the mesentery, the stomach, the anterior margin of the liver, and the gall-bladder are insensitive, and may be cut or even burned without pain.\(^1\)

Viscera which obtain their innervation purely from visceral nerves are insensitive; those which receive branches from somatic nerves are sensitive (Lennander).

The oblique origin of the mesentery causes this structure to form a sort of shelf. A hemorrhage or extravasation into the abdomen, to the right of the mesentery, tends to flow into the right iliac fossa; one occurring on the left side flows into the pelvis. Monks points out that in flushing the abdominal cavity the tube should not be aimlessly introduced, but should utilize the mesentery on each side of an intestinal loop, to "conduct the tip of the irrigating tube to the bottom of the two fossae." Monks also shows how the mesentery can be utilized to determine the direction of an intestinal loop:

"Now, let us suppose that the surgeon has between his fingers a loop of bowel, and wishes to determine its direction. He knows that one side of the loop is the left side of the intestine, and that the corresponding side of the mesentery, if closely followed down to the mesenteric root, will conduct him into the left fossa; he also knows that the other side of the bowel is its right side, and that the mesentery on that side will conduct him into the right fossa. Now,

if his finger goes into the great fossa on the left side of the abdomen, after having closely followed the mesentery down to its root and arranged his loop to be parallel with that root, he then knows that the left and right sides of the intestine face to the left and right sides of the abdomen respectively, and that the end of the loop which points downward is the end nearest the ileocecal valve. He can determine the direction of the gut in a similar way in case his finger enters the right fossa. All this would seem very simple were it not for the twists in mesentery and intestine, which tend to mislead one. A little practice will usually enable one to recognize a twist in the mesentery. This should be untwisted by rotation of the gut, after which the direction is determined by another palpation of the mesenteric root."\(^2\)

\(^2\) Intestinal Localization, by George H. Monks, Annals of Surgery, October 1903.

\(^3\) Annals of Surgery, October, 1903.
The studies made of the arrangement and variations of the loops of the mesenteric vessels by Dr. Thomas Dwight\(^1\) have been utilized and expanded by Dr. George H. Monks in laying down rules for the determination of the exact portion of small intestine which may be in the surgeon's hand.\(^2\) His views are as follows:

"**General Vascularity of the Mesentery near the Bowel.**—Opposite the upper part of the bowel the mesenteric vessels are distinctly larger than opposite any other part of it. These vessels grow smaller and smaller as we pass downward until the lower third of the gut is reached, where they remain about the same size as far as the ilio-cæcal valve. The arrangement of the mesenteric

\(^{1}\) Reports of the Meeting of American Anatomists, 1897.

\(^{2}\) Annals of Surgery, 1903.
vessels has some features which intimately concern the subject in hand, and which I shall describe with some detail. Diagrammatically speaking, the main branches of the superior mesenteric artery unite with each other by means of loops, which are called for convenience 'primary loops;' in some parts of the tube, 'secondary loops;' and even, occasionally, 'tertiary loops' are super-

Fig. 872.—A loop of intestine at twelve feet. The vessels are smaller. The primary loops are lost in the fat, but secondary and even tertiary loops are visible. The vasa recta are shorter, more irregular, and branching. (The specimen came from the same subject which furnished Figs. 869 and 871.) (Monks.)

imposed upon these. From these loops little straight vessels—the vasa recta already referred to—run to the bowel, upon which they ramify, alternating, as a rule, as to the side of the intestine which they supply. The mesenteric veins are arranged in a manner somewhat similar to the arteries.

Fig. 873.—A loop of intestine at seventeen feet. The mesentery is opaque, and small tabs of fat begin to appear along the mesenteric border of the gut. The vessels are represented by a somewhat complicated network, and are seen with difficulty in the thick fat of the mesentery. (The specimen came from the subject which furnished Figs. 869, 871, and 872.) (Monks.)

"The Loops of the Mesenteric Vessels (Figs. 869, 870, 871, 872, and 873).—Opposite the upper part of the bowel there are only primary loops. Occasionally a secondary loop appears, but it is small and insignificant as compared with the primary loops, which are large and quite regular. As we proceed down the bowel secondary loops become more numerous, larger, and approach
nearer to the bowel than the primary loops in the upper part. As a rule, secondary loops become a prominent feature at about the fourth foot. As we continue farther downward, the secondary loops (and, possibly, tertiary loops) become still more numerous and the primary loops smaller, the loops all the time getting nearer and nearer to the gut. Opposite the lower part of the gut the loops generally lose their characteristic appearance, and are represented by a complicated network.

"The Vasa Recta.—Opposite the upper part of the intestine the vasa recta are from three to five centimetres long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than one centimetre in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery."

**Fig. 874.**—A loop of intestine at twenty feet. The gut appears to be thick and large. The mesentery is quite fat and opaque, and large and numerous fat-tabs are present. The vessels, which are complicated, are seen with difficulty, and are represented by mere grooves in the fat. (The subject was a stout woman, and the entire length of the gut was twenty-one feet.) (Monks.)

The translucency of the mesentery varies greatly; in some parts it may be almost transparent, in others almost or quite opaque. Its thinnest part is above. It is thickened below by fat, fibrous tissue, and muscular tissue. In very fat subjects it may be impossible to see the vessels (Monks). According to Monks, if a loop is raised and looked at against the light close to the gut "little transparent spaces" are seen between the vasa recta, and even in the thickest mesentery; some of these "lunettes" exist along the upper portion of the intestine. As we descend in our examination, they grow smaller and become fatty, and disappear about the eighth foot of the intestine. The same author shows that the mesentery of the lower third of the intestine, except in the thinnest individuals, contains little collections of fat on the border of the mesentery, which project toward the bowel and may even extend upon it.

**THE STOMACH (VENTRICULUS) (Figs. 861, 875, 876, 878, 879).**

The stomach is the principal organ of digestion. It is the most dilated part of the alimentary canal, and is situated between the termination of the oesophagus (cardia) and the commencement of the small intestine. Its form varies because of varied conditions, but, as a rule, it is somewhat pyriform. It is placed, in part, immediately behind the anterior wall of the abdomen and beneath the Diaphragm. Viewing the stomach from in front it appears that the right margin of the oesophagus is continued downward as the upper two-thirds of the lesser curvature of the stomach, the remaining third of this border bending sharply

---

1 Annals of Surgery, October, 1903.
backward and to the right, to complete the smaller curvature (Fig. 875). The greater curvature begins at the left border of the termination of the oesophagus in a somewhat acute angle; it then passes upward and to the left to the under surface of the Diaphragm, with which it lies in contact for some distance, and then sweeps downward with a convexity to the left, and, continued across the middle line of the body, finally turns upward and backward, to terminate at the commencement of the small intestine. It will thus be seen that the stomach may be divided into a fundus (fundus ventriculi) and a middle portion or body (corpus ventriculi). The portion of the body adjacent to the cardia being known as the cardiac portion (pars cardiaeae), the long axis of which is directed downward with a slight inclination forward and to the right; and the portion adjacent to the pylorus being known as the pyloric portion (pars pylorica), the long axis of which is horizontal with an inclination backward. Of the two openings, the cardiac orifice, by which it communicates with the oesophagus, is situated slightly to the left of the middle line of the body to the right of the fundus, or dilated upper extremity of the stomach, and is directed downward; the other, the pyloric orifice, by which it communicates with the small intestine, is on a lower plane, close to the right of the mid-line, and looks directly backward.

Relations of the Stomach.—The stomach lies in a space or chamber called the stomach chamber (Fig. 861). When distended the viscus completely fills the space. When the stomach is empty it lies upon the floor of the chamber, and the portion it has vacated is occupied by the transverse colon, which ascends in front of the stomach and finally gets above it. The anterior wall of the stomach chamber is formed by the anterior abdominal wall. The root is formed by the under surface of the Diaphragm and the under surface of the left lobe of the liver. The floor is formed by the left suprarenal capsule and the summit of the left kidney, the gastric face of the spleen, the upper surface of the pancreas, the transverse mesocolon, and the colon.

Surfaces.—The stomach has two surfaces, called anterior and posterior surfaces, and two borders, termed the greater and lesser curvatures.

In regard to the so-called anterior and posterior surfaces of the stomach, it must be borne in mind that these names are not strictly correct, as the anterior surface has a certain amount of inclination upward and the posterior downward.

The Anterior, Upper or Parietal Surface (paries anterior).—The anterior surface is directed forward and to the right side. It has a somewhat flattened appearance when the stomach is empty, but when it is full the surface becomes convex. It is in relation with the Diaphragm; the thoracic wall formed by the anterior parts of the seventh, eighth, and ninth ribs of the left side; the left lobe of the liver; and the anterior abdominal wall. Between the part covered by the liver and that covered by the left ribs there is a triangular segment of the anterior wall of the stomach, which is in contact with the abdominal wall and is the only part of the stomach which is visible when the abdominal wall is removed and the viscera allowed to remain in situ. Its area is about 40 sq. cm., and it is of great importance to the surgeon, as the stomach can readily be reached in this situation. Occasionally the transverse colon may be found lying in front of the lower part of the anterior surface of the stomach. The whole of this surface of the stomach is covered by peritoneum.

1 Prof. Birmingham in Prof. Cunningham’s Text-book of Anatomy.
The Posterior, Lower or Visceral Surface (paries posterior).—The posterior surface of the stomach is directed backward and to the left. It is in relation with the Diaphragm, the gastric surface of the spleen, the left suprarenal capsule, the upper part of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the ascending layer of the transverse mesocolon. These structures form a shallow concavity or bed, on which this surface of the stomach rests. The transverse mesocolon intervenes between the stomach and the duodeno-jejunal junction and commencement of the ileum. Its greater curvature is in relation with the transverse colon and has attached to it the anterior two layers of the great omentum. Almost the whole of this surface is covered with peritoneum, but behind the cardiac orifice there is a small portion of the stomach which is uncovered by peritoneum and is in contact with the Diaphragm and frequently with the upper portion of the left suprarenal capsule.

The Lesser Curvature (curvatura ventriculi minor).—The lesser curvature of the stomach extends between the cardiac and pyloric orifices along the right border of the organ. It descends in front of the left crus of the Diaphragm, along the left side of the eleventh and twelfth dorsal vertebrae, and then turning to the right it crosses the first lumbar vertebra and ascends to the pylorus. It gives attachment to the two layers of the gastro-hepatic omentum, between which blood-vessels and lymphatics pass to reach the organ.

The Greater Curvature (curvatura ventriculi major).—The greater curvature of the stomach is directed to the left, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice, it forms an arch to the left with its convexity upward, the highest point of which is on a level with the costal cartilage of the sixth rib of the left side. It then passes nearly straight downward, with a slight convexity to the left, as low as the costal cartilage of the ninth rib, and then turns to the right to end at the pylorus. As it crosses the median line the lowest edge of the greater curvature is about two fingers' breadth above the umbilicus. The lower part of the greater curvature gives attachment to the two anterior layers of the great omentum, between which layers vessels and lymphatics pass to the organ.

The Cardia (Fig. 876).—The cardia is the point at which the oesophagus enters the stomach wall. The opening is called the cardiac orifice or the oesophageal opening. At the cardia the circular muscular fibres constitute a sphincter.

The Cardiac Orifice (Fig. 876).—The cardiac orifice is the opening by which the oesophagus communicates with the stomach. It is therefore sometimes termed the oesophageal opening. It is the most fixed part of the stomach, and is situated about two inches below the highest part of the fundus on a level with the body of the tenth or eleventh dorsal vertebra to the left and a little in front of the aorta. This would correspond on the anterior surface of the body to the articulation of the seventh left costal cartilage to the sternum. It is placed far off from the surface and is at least four inches back of the seventh left chondro-sternal articulation.

The Pylorus (Fig. 876).—The pylorus is the point at which the stomach passes into the duodenum. The opening of communication is called the pyloric orifice. At the pylorus the muscular fibres constitute a sphincter.

The Pyloric Orifice (Fig. 876).—The pyloric orifice communicates with the duodenum, the aperture being guarded by a valve (Fig. 877). Its position varies with the movements of the stomach. When the stomach is empty the pylorus is situated just to the right of the median line of the body, on a level with the upper border of the first lumbar vertebra. On the anterior surface of the body its position would be indicated by a point one inch below the tip of the ensiform cartilage and a little to the right. As the stomach becomes distended the pylorus moves to the right, and in a fully distended stomach may be situated two or three inches to the right of the median line. The direction of the pylorus is upward and to
the right, which position prevents "the weight of the gastric contents bearing directly on the sphincter apparatus." Near the pylorus the stomach frequently exhibits a slight dilatation, which is named the antrum of the pylorus (antrum pyloricum). The pylorus is indicated by a constriction, the direction of which is circular. The pylorus lies upon the neck of the pancreas behind. Above it and in front of it is the liver.

The size of the stomach varies considerably in different subjects. When moderately distended its greatest length, from the top of the fundus to the lowest part of the greater curvature, is from ten to twelve inches and its diameter at the widest part from four to five inches. The distance between the two orifices is three to six inches, and the measurement from the anterior to the posterior wall three and a half inches. Its weight, according to Clendinning, is about four ounces and a half, and its capacity in the adult male is five to eight pints. The stomach of a newborn child holds about one ounce.

**Alterations in Position.**—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. When empty, it lies at the back part of the abdomen, some distance from the surface, and is in the left hypochondriac region and the left portion of the epigastric region. Its fundus is directed upward and backward toward the Diaphragm. The long axis of the viscus is nearly horizontal. Its pyloric end is directed upward and backward, is situated close to or very slightly to the right of the middle line, covered in front by the left lobe of the liver, and being on a level with the first lumbar vertebra. When empty, the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end. The entire viscus is small and contracted, and the pyloric region resembles the intestine. When the stomach is distended, its surfaces, which are flattened when the organ is empty, become convex and the shape becomes pyriform. The viscus becomes very oblique and approaches the vertical,

---

1 W. J. Mayo, Medical Record, June 11, 1904.
its long axis being downward, forward, and to the right. The greater curvature is elevated and carried forward, so that the anterior surface is turned more or less upward and the posterior surface downward, and the stomach is brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice; in doing this the Diaphragm is forced upward, contracting the cavity of the chest; hence the dyspnea complained of, from inspiration being impeded. The apex of the heart is also tilted upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. The left lobe of the liver is pushed to the right side. When the stomach becomes distended the change in the position of the pylorus is very considerable; it is shifted to the right, some two or three inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distention of the stomach the lesser cul-de-sac bulges over the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backward. When the stomach is greatly distended its lower border may enter the umbilical and the left lumbar regions. During inspiration the stomach is displaced downward by the descent of the Diaphragm, and it is elevated by the pressure of the abdominal muscles during expiration. Pressure from without, as from tight lacing, pushes the stomach down toward the pelvis. In fact, in the female, because of tight lacing, the stomach may be to the left side of the vertebral column and nearly vertical in direction, the lower portion being sharply angled upward toward the pylorus, which lies underneath the liver. Besides the angulation, the lower end, the stomach may have a median constriction, and there may even be an hour-glass stomach. The descent of the stomach from tight lacing may cause the pancreas to become nearly vertical. In disease the position and connection of the stomach may be greatly changed, from the accumulation of fluid in the chest or abdomen, or from alteration in size of any of the surrounding viscera.

Variations according to Age.—In an early period of development the stomach is vertical, and in the newborn child it is more vertical than later on in life, as owing to the large size of the liver it is more pushed over to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

On looking into the pyloric end of the stomach, the mucous membrane is found projecting inward in the form of a circular fold, the pyloric valve (Fig. 877), leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The Pyloric Valve (valvula pylori) (Fig. 877).—The pyloric valve is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular fibres, which are aggregated into a thick circular ring, the pyloric sphincter (m. sphincter pylori); the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation (Fig. 877). The pylorus is normally kept closed by the action of this aggregation of circular fibres which constitutes the Sphincter muscle. During the early stage of digestion it remains closed, but after a time opens now and then. The opening becomes more frequent and the period of patency is prolonged as digestion advances.

The diameter of the pylorus is uncertain. It is usually said to be half an inch. But it is closed when the pylorus is at rest, and it can certainly dilate even in a child to at least an inch and let bodies of this size pass through.

The Peritoneum.—The great omentum comes off from the greater curvature of the stomach and passes to the transverse colon. The lesser omentum comes off from the lesser curvature and passes to the liver. The gastro-splenic ligament or omentum passes from the under surface of the stomach just below the greater curvature to the spleen. A fold of peritoneum passes up from the stomach along the left side of the oesophagus to the Diaphragm. This is the gastro-phrenic ligament.

Supports of the Stomach.—The stomach lies on the bed of the stomach chamber, which was described on p. 1269. The great omentum gives no support to the stomach, neither does the gastro-splenic ligament, because of the movability of the spleen. The lesser omentum does give support to the stomach and so do
the gastro-phrenic ligament and the hepato-duodenal ligament. The two chief points of support are the attachment of the oesophagus to the Diaphragm and the fixation of the duodenum to the front of the vertebral column.

**Structure.**—The wall of the stomach consists of four coats: serous, muscular, areolar, and mucous, together with vessels and nerves.

The Peritoneal or Serous Coat (*tunica serosa*).—The peritoneal or serous coat covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; at each curvature the two layers of peritoneum leave a small triangular space, to which the peritoneum is not attached, although it is attached in front of it and back of it. Along these spaces the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice and below and to the left of it, there is a smaller triangular area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm, and it may be

Fig. 878.—The superficial muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

with the left suprarenal body and the summit of the left kidney. When the stomach is moderately distended this *uncovered area* measures about one and a half inches from above downward, and about two inches from before backward. At the left angle of this uncovered area the insertion of the great omentum begins. At the right angle the gastric artery reaches the stomach.

The Muscular Coat (*tunica muscularis*) (Figs. 878 and 879).—The muscular coat is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of fibres—*longitudinal, circular, and oblique*.

The Longitudinal Fibres (*stratum longitudinale*) are most superficial; they are continuous with the longitudinal fibres of the oesophagus, radiating in a stellate
manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine. The bundles of longitudinal muscle-fibre on the upper and lower surfaces of the pylorus are particularly firm and distinct, and are called the pyloric ligaments (ligamenta pylori).

The Circular Fibres (stratum circulare) form a uniform layer over the whole extent of the stomach, except the fundus, beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring or sphincter (m. sphincter pylori), which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the pyloric valve (valvula pylori) (Fig. 877). They are continuous with the circular fibres of the oesophagus.

The Oblique Fibres (fibrae obliquae) arise at the left side of the cardia from the circular fibres of the oesophagus. The fibres pass down in the anterior and posterior walls. Those of the anterior wall are parallel to the lesser curvature and almost reach the pylorus. Those of the posterior wall are more nearly transverse to the long axis of the stomach (Spalteholz). These fibres gradually assume the direction of the circular fibres and terminate in them. The layer of oblique fibres is beneath the circular layer. Certain oblique muscular fibres encircle the fundus of the stomach in a series of rings.

The Areolar or Submucous Coat (tela submucosa).—The areolar or submucous coat consists of loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It supports the blood-vessels previous to their distribution to the mucous membrane; hence it is sometimes called the vascular coat.
The Mucous Membrane (tunica mucosa) (Figs. 880, 881, and 882).—The mucous membrane is thick; its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown color over the rest of the surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugae (plicae mucosae) (Figs. 880 and 882 A), which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature, and which contain also submucous tissue. These folds are entirely obliterated when the organ becomes distended. A constant fold exists at the pylorus (Fig. 877). It is called the pyloric valve, and is produced by the presence beneath it of the Sphincter muscle. Besides the large folds or rugae and the pyloric valve, there are numerous small elevations of mucous membrane known as gastric areas (areae gastricae), which are partly separated from each other by furrows and which vary greatly in shape (Fig. 880). According to Spalteholz, each one of these elevations has an area of several square millimetres.
Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions or alveoli (foveolae gastricae) (Figs. 881 and 882, B) of a polygonal or hexagonal form, which vary

Fig. 882.—The mucous membrane of the stomach. A, natural size; B, magnified 25 diameters. In A the rugae and the mammillated surface are shown. In B the gland mouths (foveolae gastricae), with the gland tubes leading from some of them, and the ridges separating the mouths (plica villosae) are seen. (Cunningham.)

Fig. 883.—Pyloric gland.

Fig. 884.—Peptic gastric gland.
from $\frac{1}{100}$ to $\frac{1}{2}$ of an inch in diameter, and are separated by slightly elevated ridges (plicae villosoae). The ridges are most distinct at the pylorus. These foveolae are within the areae gastricae. The ridges on section resemble villi. In the bottom of the alveola are seen the orifices of minute tubes, the gastric glands (Fig. 882 B), which are placed perpendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of columnar epithelium; it lines the alveoli, and also for a certain distance the mouths of the gastric glands. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the stratified epithelium of the oesophagus. The cells are elongated, and consist of two parts, the inner or attached portions being granular, and the outer or free parts being clear and occupied by a mucous albuminous substance.

The Gastric Glands.—The gastric glands are of three kinds: the true gastric glands, the pyloric glands, and the cardiac glands.

The True Gastric Glands (Fig. 884) are called also the oxyntic glands, the fundus glands, and the peptic glands (glandulae gastricae propriae). They are distributed throughout the entire fundus and body, and may be found even at the pylorus. They are tubular in character, and are formed of a delicate basement-membrane, lined with epithelium. The basement-membrane consists of flattened transparent endothelial cells, with processes which extend between and support the epithelium. Into the crypt of a true gastric gland three or more caecal tubes, branched or unbranched, empty. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the chief or the peptic or the central cells of the glands, and furnish pepsin. Between these cells and the basement-membrane are found other darker granular-looking cells, studded throughout the tubes at intervals, and giving it a beaded or varicose appearance. These are known as the parietal or oxyntic cells. Some of the parietal cells empty directly into the lumen of the gland by secretory capillaries; others empty by a duct which divides into secretory capillaries. The parietal cells secrete the acid of the gastric juice. Between the glands the mucous membrane consists of a connective-tissue framework with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the lenticular glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands.

The Pyloric Glands (glandulae pyloricae) (Fig. 883) are the branched tubular glands, and secrete mucus. They are placed most plentifully about the pylorus, but between the fundus and pylorus, in the region known as the transitional or intermediate zone, both true gastric glands and pyloric glands are found. Each pyloric gland consists of two or three short, closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The caecal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The pyloric glands branch more frequently, are more curved in direction, and open into deeper foveolae than the true gastric glands (Szymonowicz). They contain only chief or peptic cells and do not possess parietal cells.
The Cardiac Glands are found about the oesophageal orifice. They resemble the pyloric glands.

Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (muscularis mucosae), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner circular, and an outer longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are—the gastric or coronary, the pyloric and the right gastro-epiploic branch of the gastro-duodenal, the left gastro-epiploic and vasa brevia from the splenic. The gastric artery passes to the lesser curvature just below the cardia. It gives off the oesophageal branch, and passes from left to right along the lesser curvature of the stomach beneath the peritoneum between the two layers of the lesser omentum and upon the wall of the stomach. It may in this course be a single vessel, or may divide into two branches, which run along each side of the lesser curvature (Fig. 886). If there is a single artery it gives off six or seven descending branches to the anterior wall and about the same number to the posterior wall of the stomach. It also gives branches to the lesser omentum. If two vascular arches form, one gives branches to the anterior wall of the stomach, the other to the posterior wall, and both to the lesser omentum. The termination of the gastric anastomoses with the pyloric branch or two rami of the pyloric branch of the hepatic artery. From each arch six or seven descending branches come off to the anterior and posterior walls of the stomach. The gastro-duodenal artery is given off by the hepatic. From the gastro-duodenal comes the right gastro-epiploic. The left gastro-epiploic comes from the splenic. The right gastro-epiploic artery passes from right to left in the gastro-colic omentum below the greater curvature of the
The **gastro-epiploic artery** passes forward in the gastro-splenic ligament to below the greater curvature of the stomach, and passes from left to right along that curvature in the gastro-colic omentum, and joins the right gastro-epiploic artery. The gastro-epiploic arteries are not upon but are distinctly below the stomach wall. From them numerous gastric branches are sent to the anterior and posterior walls of the stomach, and they anastomose with branches of the gastric and pyloric. Vasa brevia, four or five in number, arise from the splenic, pass forward in the gastro-splenic ligament, and supply the fundus. The arteries of the stomach lie first beneath the peritoneum, but soon enter the muscular coat, supply it, pierce it, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar (Fig. 885). The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli.

The capillary networks about the glands give origin to the **veins**. The various small veins unite and form a plexus in the submucous tissue (Fig. 885). From this plexus come branches which pass through the muscular coat and terminate in the right gastro-epiploic branch of the superior mesenteric, the left gastro-epiploic branch of the splenic, the veins to the splenic which correspond to the vasa brevia arteries, and the gastric or coronary branch of the portal.

The lymphatics (Figs. 507 and 508) arise in the mucous membrane and terminate in a network in the submucous tissue. From this network trunks arise which perforate the muscular coat in the regions of the curvatures and terminate in the sero-muscular collecting trunks.¹

According to Cunéo, there are three groups of these collectors. Those from the lesser curvature pass to the point where the gastric artery reaches the stomach and enter the glands along the gastric artery. Those from the greater curvature pass from left to right and enter the sub-pyloric glands. Those from the fundus pass from right to left and end in the splenic glands. Cunéo further pointed out that the region drained by the collectors of the lesser curvature is divided from the others by the line shown in Fig. 507. This division exists on both surfaces of the stomach. The limit between the collectors which drain into the splenic glands and those which drain into the sub-pyloric glands is also shown in Fig. 507. Along the lesser curvature the lymph-glands are few in number and are limited to the pyloric region, and the lymph-vessels are placed directly upon the stomach wall. The lymph-glands and vessels are not upon but are distinctly below the greater curvature.

The subserous and submucous lymphatic networks of the stomach communicate with the corresponding networks of the oesophagus, but in all probability do not communicate with the networks of the duodenum.

The **nerves of the stomach** come from the right and left pneumogastrics and from the solar plexus of the sympathetic. The left pneumogastric passes to the front of the stomach, and the right nerve passes to the back, and they unite with the fibres of the sympathetic. The fibres thus formed are mostly non-medullated. They form Auerbach’s plexus in the muscular coat between the circular and longitudinal fibres and Meissner’s plexus in the submucous coat, the latter plexus being formed by fibres from the former. Fibres from Meissner’s plexus ramify in the submucous coat and terminate in the muscularis mucosae and the mucous membrane, branches passing to the gastric glands and to just beneath the epithelium.

¹ The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
Movements and Innervation of the Stomach.

Movements.—It has apparently been demonstrated that the stomach “consists of two parts physiologically distinct.” The cardiac portion of the stomach is a food reservoir in which salivary digestion continues; the pyloric portion is the seat of active digestion. Cannon affirms that there are no peristaltic waves in the cardiac portion, but that as the food passes from the pyloric portion into the intestines, tonic contraction of the muscles of the fundus squeezes the contents of the pyloric portion. Moritz, Levan, and Cannon assert that muscular activity is chiefly manifested in the pyloric portion. In this portion during digestion there is a succession of peristaltic waves, which waves in the human being pass at the rate of three per minute (Moritz). Cannon points out that the efficiency of post-stasis in mixing the food depends upon the contraction of the pyloric sphincter. So long as the sphincter holds, each constriction-ring coursing from the middle to the end of the stomach presses the food into a blind pouch; the food, unable to escape through the pyloric opening, has as its only outlet the opening in the advancing ring. This is an admirable device for bringing the food under the influence of the glandular secretions of the pyloric region. For, as a constriction occurs, the secreting surface enclosed by the narrowed muscular ring is pressed close around the food within the ring. As the constriction advances it continually presses inward fresh glandular tissue, and furthermore, as the constriction advances, a thin stream of food is continuously forced back through the ring and thus past the mouths of the glands. The old view that the pyloric sphincter only opens after several hours’ continuance of the process of digestion and that then the stomach empties at once is incorrect. It is emptied in small amounts which escape at frequent intervals because of the intermittent opening of the pylorus. When the pylorus is open a wave of peristalsis forces some of the material from the stomach into the duodenum (Cannon).

Cannon is of the opinion that the pyloric sphincter is caused to relax by the presence of free hydrochloric acid in the pyloric portion of the stomach. When the pylorus is open acid chyme passes into the duodenum and acid in the duodenum causes the pylorus to close. The acid in the duodenum causes a flow of alkaline pancreatic juice and the acid is neutralized. “As the neutralizing proceeds the stimulus closing the pylorus is weakened until the acid in the stomach again opens the sphincter.”

Innervation.—The stomach, as previously shown, has nervous plexuses in its walls and is connected to the brain, spinal cord, and sympathetic system. It is probable that gastric peristalsis is due to a local reflex from Auerbach’s plexus (Magnus), the local reflex being inaugurated by local stimulation, which stimulation, in the words of Bayliss and Starling, “produces excitation above and inhibition below the excited spot.” Reversed peristalsis cannot occur if “the reflex mechanism is intact” (Cannon). Cannon in the previously quoted article states that cutting the vagus or splanchnic nerves does not destroy the reflex mechanism of the pylorus, but, nevertheless, it is markedly affected by the central nervous system.

Surface Form (see p. 1271).—The cardiac orifice corresponds to the articulation of the seventh left costal cartilage with the sternum. The pyloric orifice of the empty stomach is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, as much sometimes as three inches. The fundus of the stomach reaches, on the left side, as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the distended stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrostomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed, ulcers are excised, malignant growths are removed with the associated lymphatic involvement, the entire stomach may be removed for cancer, etc. By “gastrotomy” is meant an incision into the stomach for the removal of a foreign body, or the arrest of hemorrhage or for exploration, the opening being immediately afterward closed—in contradistinction to “gastrostomy,” the making of a more or less permanent fistulous opening. Gastrotomy is probably best performed by an incision in the linea alba, especially if the foreign body is large. The cut may reach from the ensiform cartilage to the umbilicus. The incision may be made over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned shortly. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert sutures—i. e., by sutures passed through the peritoneal,

1 Walter B. Cannon, Medical News, May 20, 1905.  
2 Ibid.  
3 Ibid.
muscular and submucous coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. Gastrostomy was formerly done in two stages by the direct method. The first stage consisted in opening the abdomen, drawing up the stomach into the external wound, and fixing it there; and the second stage, performed from two to four days afterward, consisted in opening the stomach. The operation is now done by a valvular method. The following plan is known as the Sabanljew-Frank operation. An incision is commenced opposite the eighth intercostal space, two inches to the left of the median line, and carried downward for three inches. By this incision the fibres of the Rectus muscle are exposed and these are separated from each other in the same line. The posterior layer of the sheath, the transversalis fascia and the peritoneum, are then divided, and the peritoneal cavity is opened. Instead of the above incision, the curved incision of Fenger can be made at the margin of the left costal cartilages. The anterior wall of the stomach is now seized and drawn out of the wound and a silk suture passed through its submucous, muscular, and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the rectus are sutured to the base of the cone. A second incision is made through the skin, over the margin of the costal cartilage, above and a little to the outer side of the first incision. If Fenger's incision were used, the second incision should be above the margin of the cartilages. With a pair of dressing forceps a track is made under the skin through the subcutaneous tissue from the one opening to the other and the diverticulum of the stomach is drawn along this track by means of the suture inserted into it; so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex and its margin carefully and accurately sutured to the margin of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of gastric ulcer, perforation sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable percentage of cases are cured, provided the operation is undertaken within twelve to fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert sutures.

Pylorectomy or excision of the pylorus is performed, particularly for early cancer, but is also done for cicatrical stricture and for ulcer. The mortality after operation for cancer was, until recently, very great, but of late years it has been notably reduced, though it is still much higher than that which follows operation for any non-malignant condition.

In operating for cancer, bear in mind Cuneo’s study of the lymphatics (page 806). These observations indicate that the fundus and two-thirds of the greater curvature are free from lymphatic involvement in pyloric cancer. In every operable case of cancer of the pylorus the entire lesser curvature must be removed up to the gastric artery (Mikulicz’s point), and the greater curvature must be removed to the left of the involved glands (Hartmann’s rule).

Gastro-enterostomy is an operation which establishes a fistulous communication between the stomach and jejunum. The operation is often called gastro-jejunosotomy. The opening may be made upon either the anterior or the posterior wall of the stomach, between the cardia and the sentinel of pyloric disease. The operation is employed for stricture of the pylorus (benign or malignant), and occasionally for ulcer of the stomach.

Loretas operation is digital division of the pylorus for cicatrical stricture, the stomach being incised transversely near the pylorus to admit the finger, and the wound in the stomach being sutured after division has been effected. The operation has been abandoned, because contraction recurs.

Pyloroplasty, or the Heineke-Mikulicz operation, displaced Loretas operation. In this procedure an incision is made through the stricture in the direction of the long axis of the stomach and bowel. By making traction on each side of the incision, the longitudinal wound assumes a vertical direction, and sutures are inserted so as to close the wound in a vertical line. The method of pyloroplasty devised by Finney, of Baltimore, makes a large permanent opening at the most dependent part of the stomach, and is the most satisfactory method of which we are possessed.

Total gastrectomy is the removal of the entire stomach. It is only used for cancer. It was first performed by Conner, of Cincinnati. The first successful operation was done by Schlatter, of Zurich, in 1898. A number of successes have been reported. It is a justifiable operation only in a case in which almost the entire stomach is cancerous, in which the viscus is movable, in which there are no secondary deposits, and no irremovable diseased glands.

Gastro-gastrostomy is an operation employed in hour-glass stomach. In this operation an anastomosis is made between the pyloric and cardiac ends of the stomach.

2 Johns Hopkins Hospital Bulletin, July, 1902.
**THE ORGANS OF DIGESTION**

*Gastroplication* is the operation of suturing the stomach wall into folds or reefs, in order to lessen its size. It is employed in some cases of gastric dilatation.

*Gastroptosis* is a condition in which the stomach is displaced downward. In some of these cases the greater curvature almost reaches the level of the symphysis pubis, and the lesser curvature is midway between the umbilicus and ensiform cartilage. The condition is usually associated with *enteroptosis* and movable kidney (nephroptosis). In this condition the gastro-hepatic omentum and the gastro-phrenic ligament are pulled upon and lengthened. The best operation for gastropptosis was devised by Beyea. He applies sutures so as to make folds in and thus shorten the stretched ligament and omentum. Thus the stomach is elevated to its proper position, and its mobility is not lessened, as it is in other operations which suture it to the abdominal wall.

**THE SMALL INTESTINE (INTESTINUM TENUE).**

The small intestine is a convoluted tube, extending from the pylorus to the ileo-caecal valve, where it terminates in the large intestine. It fills up the greater part of the abdominal cavity and of the pelvic cavity. It is about twenty feet in length, and gradually diminishes in size from its commencement to its termination. The diameter of the duodenum is almost two inches; the diameter of the lower portion of the small intestine is little more than one inch. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum; it is in relation, in front, with the great omentum and abdominal parietes; and connected to the spine by a fold of peritoneum, the *mesentery* (p. 1257). The small intestine is divisible into three portions—the duodenum, the jejunum, and ileum.

**The Duodenum** (Figs. 887, 892, 893, 894, 895).

The duodenum has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine, being closely and firmly attached to the posterior abdominal wall. It does not possess a mesentery. Somewhat more than the upper half of the duodenum is placed in the epigastric region; the remainder is in the umbilical region. The duodenum, with the exception of the ascending portion, is to the right of the median line. Its course presents a remarkable curve, which in the adult, as regards the greater part of its extent, is horseshoe-shaped, though sometimes, in consequence of the transverse portion being very short or altogether wanting, it partakes more of the character of the letter V. The opening of the horseshoe being directed upward and to the left. In children up to the age of about seven the duodenum is annular. The two extremities of the duodenum are nearly on the same level, the exit being slightly lower than the entrance. The two ends are about two inches apart; and between them it describes a regular curve embracing the head of the pancreas, the neck of which lies between the two extremities of the ring.

In the adult the course of the duodenum is as follows: commencing at the pylorus the direction of the first portion depends upon the amount of distention of the stomach and therefore upon the position of the pylorus. When the stomach is empty and the pylorus is situated at the right of the upper border of the first lumbar vertebra, it is nearly horizontal and transverse; but where the stomach is distended, in consequence of the alteration of the position of the pylorus to the right the proximal end of the duodenum also becomes altered in position, while the

---

1 Trveys states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowels is independent, in the adult, of age, height, and weight.—*En. of 16th English edition.*
distal end remains fixed and the direction of this portion of the bowel is now antero-posterior. Whether directed transversely or antero-posteriorly, it reaches the under surface of the liver, where it takes a sharp curve and descends along the right side of the vertebral column, for a variable distance, generally to the body of

---

1 In the subject from which the cast was taken the left kidney was lower than normal.
the fourth lumbar vertebra. It now takes a second bend, and passes across the
front of the vertebral column from right to left and finally ascends on the left side
of the vertebral column and aorta to the level of the upper border of the second
lumbar vertebra and there terminates in the jejunum. As it unites with the
jejunum it often turns abruptly forward, forming the **duodeno-jejunal angle**. Prof.

Birmingham points out that the incomplete ring formed by the duodenum does
not lie throughout in the same plane. "Its greater part is placed in a transverse
vertical plane; the middle portion bends strongly backward, around the right side
of the vena cava, and lies almost in a sagittal plane." From the above description
it will be seen that the duodenum may be divided for purposes of description
into four portions—**superior, descending, transverse and ascending**.

The **First or Superior Portion** (pars superior) (Figs. 887, 892, and 894) is
very variable in length, but is usually estimated as being about two inches.
Beginning at the pylorus, it ends at the level of the neck of the gall-bladder.

---

1 Prof. Cunningham's Text-book of Anatomy.
When the stomach is empty this portion of the duodenum is horizontal and transverse; when the stomach is distended it extends from before backward. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum. A small part of its posterior surface is not completely covered by peritoneum (Fig. 888). The first inch of the superior portion of the duodenum is completely covered by peritoneum; the lesser omentum is attached above and the greater omentum below (Fig. 888). The other portion has only its anterior wall covered by peritoneum. The posterior and lateral surfaces are uncovered by peritoneum and are near the neck of the gall-bladder and the inferior vena cava. The first portion of the duodenum is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation above and in front with the quadrato lobe of the liver, lying in a slight concavity, the impressio duodenalis. It is also in relation above in part with the gall-bladder; behind with the gastro-duodenal artery, the common bile-duct, and the vena porta; and below with the head of the pancreas. The superior portion of the duodenum crosses the transverse fissure of the liver, and by means of the superior flexure of the duodenum (flexura duodeni superior) passes into the second or descending portion beneath the caudate lobe.

The **Second** or **Descending Portion** (pars descendens) (Figs. 887, 892, and 894) is between three and four inches in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The portions of the descending part of the duodenum above and below this interspace are named the supracolic and infracolic portions, and are covered in front by peritoneum (Fig. 889). The right side of the supracolic portion is covered by peritoneum derived from the anterior surface of the right kidney, the left side of the same portion being covered by the peritoneum forming the lesser sac. The infracolic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is uncovered by peritoneum. The descending portion of the duodenum is in relation, in front, with the transverse colon, and above this with the right lobe of the liver, where it lies in the impressio duodenalis for the second part of the duodenum; behind with the front of the right kidney, to which it is connected by loose areolar tissue, the renal vessels and the vena cava inferior; at its inner side is the head of the pancreas, and the ductus communis choledochus; to its outer side is the hepatic flexure of the colon. The common bile-duct passes downward behind the first portion of the duodenum, descends to the inner side of the second portion, is joined by the pancreatic duct, and the two ducts perforate the inner side of this portion of the intestine obliquely, and empty into the duodenum by a common opening or by two openings at the summit of a papilla, some three or four inches below the pylorus. The relations of the second part of the duodenum to the right kidney present considerable variations. The descending portion passes into the transverse portion by means of the flexura duodeni inferior.

The **Third, Pre-aortic, Horizontal or Transverse Portion** (pars horizontalis inferior) (Figs. 887, 892, and 894) varies much in length; when the duodenum assumes the ordinary horseshoe form, it measures from two to three inches; but when it presents the rarer V-shaped form, it is practically wanting or very much reduced in length. The transverse portion is described as the horizontal part of the ascending or last portion by those authors who divide the duodenum into three parts instead of four. It commences at the right side of the fourth lumbar vertebra and passes from right to left, with a slight inclination upward, in front of the great
vessels and crura of the Diaphragm, and ends in the fourth portion in front of or just to the left of the abdominal aorta. It is crossed by the superior mesenteric vessels and mesentery. The posterior surface rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm. By its upper surface this portion of the duodenum is in relation with the head of the pancreas. The front of the third portion of the duodenum is covered by peritoneum except where the mesenteric vessels and root of the mesentery cross it (Fig. 890). The left side of the termination of the ascending portion is also covered by peritoneum, and in this region the duodenal fossae are found (p. 1260).

The Fourth or Ascending Portion of the Duodenum (pars ascendens) (Figs. 887, 892, and 894) is about two inches long. It ascends on the left side of the vertebral column and aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly to the right and forward to become the jejunum, forming the duodeno-jejunal angle or flexure (flexura duodenojejunalis) (Fig. 892). It is covered entirely in front and partly at the sides by peritoneum, derived from the left portion of the mesentery (Fig. 891). The superior mesenteric artery and vein are in front of it. It touches the left kidney, slightly overlapping its inner margin, and rests upon the left crus of the Diaphragm.

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodeno-jejunal flexure is further bound down and fixed by a structure called the Suspensory muscle of the duodenum or the suspensory ligament of Treitz (m. suspensorius duodeni) (Fig. 892). This structure commences in the connective tissue around the coeliac axis and left crus of the Diaphragm, and passes downward to be inserted into the superior border of the duodeno-jejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, some few plain muscular fibres mixed with the
fibrous tissue, of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

**Fig. 893.—The interior of the duodenum. (Spalteholz.)**

**Fig. 894.—The duodenum, its four parts marked a, b, c, d. The liver is lifted up; the greater art of the stomach is removed, broken lines indicating its former position. (Testut.)**
**Interior of the Duodenum** (Fig. 893).—In the beginning of the duodenum valvulae conniventes are absent. They begin to appear in the lower half of the first portion, being at first trivial elevations irregularly placed. They become higher, regular, and more numerous lower down, and near the termination of the duodenum are strongly marked and closely placed transverse or spiral folds (Fig. 893 and p. 1291). In the descending portion (Fig. 893) to the side and rear is a longitudinal fold (*plica longitudinalis duodeni*), which is formed by the projection of the bile-duct and pancreatic duct beneath the mucous membrane.

The *caruncula major of Santorini* or the *bile papilla* is a projection or pit in the lower part of the longitudinal fold. At the summit of this papilla are seen two openings, if the bile-duct and pancreatic duct have not united, or one common opening for both of them, if they have united. One inch above and half an inch or more in front of the bile papilla is a much smaller papilla, the *caruncula minor of Santorini* (*papilla duodeni [Santorini]*) on the summit of which the accessory pancreatic duct of Santorini opens.

**Structure of the Duodenum.**—The *peritoneal coat* (*tunica serosa*) has been described. The *muscular coat* (*tunica muscularis*) is practically identical with the muscular coat of the balance of the intestine. The bile-duct and pancreatic duct pass through it. The *submucous coat* (*tela submucosa*) contains lymph-nodes and *glands of Brunner* (*glandulae duodenales*). These glands are particularly plentiful in the first half of the duodenum (p. 1295). The mucous membrane is thicker in the duodenum than in the rest of the small intestine, is covered with villi, and from the lower half of the first portion down is formed into circular folds or valvulae conniventes. In the descending part it exhibits the previously described longitudinal fold.

**Vessels and Nerves.**—The *arteries* (Fig. 895) supplying the duodenum are the pyloric and pancreatico-duodenal branches of the *hepatic*, and the *inferior pancreatico-duodenal branch of the superior mesenteric*. The *veins* (Fig. 895) correspond to the arteries. The *superior duodenal vein* passes into the superior mesenteric, and the *inferior duodenal vein* passes into the portal. The *lymphatics* pass along with the pancreatico-duodenal arteries, glands being present here and there, and terminate in the glands about the *coeliac axis*. The *duodenal fossae* are described on p. 1260. The *nerves* are derived from the solar plexus.
The Jejunum and Ileum (Figs. 862, 864, 865, 867, 892).

The remainder of the small intestine from the termination of the duodenum comprises the jejunum and ileum; the former name being given to the upper two-fifths and the latter to the remaining three-fifths. Spalteholz and others call all of the small intestine below the duodenum the intestinum tenue mesenteriale. There is no morphological line of distinction between the jejunum and ileum, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows:

**Differences between the Jejunum and Ileum.**—If the jejunum high up is contrasted with the ileum low down, it is noted that the former is thicker, of greater diameter, contains more blood-vessels, and hence is more distinctly red, has well-marked valvulae conniventes, but a few small-sized Peyer's patches, and the villi are short and broad. In the ileum large Peyer's patches are present in numbers, and the villi are thin (Prof. Birmingham).

**The Jejunum** (intestinum jejunum).—The jejunum, which derives its name from the Latin word jejunus (empty), because it was formerly supposed to be empty after death, is wider, its diameter being about one inch and a half, and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. Its valvulae conniventes are large and thickly set and its villi are larger than in the ileum. The glands of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. Brunner's glands are only found in the upper part of the jejunum. By grasping the jejunum between the finger and thumb the valvulae conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

**The Ileum** (intestinum ileum).—The ileum (so called from the Greek word σιλειν, to twist, on account of its numerous coils and convolutions) is placed below and to the right of the jejunum. It is narrower, its diameter being one inch and a quarter, and its coats are thinner and less vascular than those of the jejunum. It possesses but few valvulae conniventes, and they are small and disappear entirely toward its lower end, but Peyer's patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The upper portion of the jejunum passes to the left of the duodeno-jejunal flexure, and is in relation with the under surface of the pancreas and the transverse mesocolon. The lower portion of the ileum is in the pelvis and rises from above the brim, passing upward, backward, and to the right to reach the ilico-caecal opening. Treves points out that another portion of the small intestine may be in the pelvis, viz., the portion with the longest mesentery. This is a portion somewhere between a point six feet from the duodenum and a point eleven feet from the duodenum. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the mesentry (p.1257), which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border, about six inches in length, is attached to the abdominal wall from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 862). Its length is about eight inches from its commencement to its termination at the intestine, and it is rather longer about its centre than at either end of the bowel. According to Lockwood,
it tends to increase in length as age advances. Between the two layers of which it is composed are contained blood-vessels, nerves, lacteals, and lymphatic glands, together with a variable amount of fat.

**Meckel's Diverticulum (diverticulum ilei).**—Occasionally there may be found connected with the lower part of the ileum, on an average about three feet from its termination, a blind diverticulum or tube, varying in length, but averaging about two inches, and being of about the same diameter as the piece of intestine of which it is a part. Sometimes only a portion of the proximal end is open and the balance of the structure is obliterated and shrunk to a fibrous cord. In other cases the diverticulum is actually of greater diameter than the intestine. It usually is at a right angle to the intestine, but may take almost any direction. In most cases it has a mesentery. It is attached to and communicates with the lumen of the bowel by one extremity, and by the other is unattached or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the vitelline or omphalo-mesenteric duct, the duct of communication between the umbilical vesicle and the alimentary canal in early fetal life.

**Structure of the Small Intestine, including the Duodenum.**—The wall of the small intestine is composed of four coats—serous, muscular, areolar or submucous, and mucous.

The **Serous Coat (tunica serosa).**—The relation of the peritoneum to the duodenum has been described. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The **Muscular Coat (tunica muscularis).**—The muscular coat consists of two layers of fibres, an external or longitudinal layer and an internal or circular layer.

The **Longitudinal Fibres (stratum longitudinal) are thinly scattered over the surface of the intestine, and are more distinct along its free border.**

The **Circular Fibres (stratum circulare) form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of plain muscle-cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.**

The **Areolar or Submucous Coat (tela submucosa).**—The areolar or submucous coat connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a bed for the subdivision of the nutrient vessels, previous to their distribution to the mucous surface.

The submucous coat contains **lymph-nodules (noduli lymphatici).** Each nodule is pyramidal or pear-shaped, and the apex lies in the mucous membrane and forms a rounded elevation. These rounded elevations mark the solitary glands and Peyer's patches (Figs. 896, 898, and 905), and in nowise resemble villi. In the duodenum the submucous tissue contains the **duodenal glands.** The submucous tissue is prolonged into the **valvulae confluentes.** It contains blood-vessels, Meissner's plexus of nerves, and lymph-vessels.

The **Mucous Membrane (tunica mucosa).**—The mucous membrane is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the **muscularis mucosae; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They are granular in appearance, and each possesses a clear, oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striae, which were formerly
believed to be minute channels by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

The mucous membrane presents for examination the following structures contained within it or belonging to it:

Valvulae conniventes. Duodenal glands.
Villi. Lymphatic nodules (Solitary glands.
Simple follicles. Peyer's or agminate glands.

The Valvulae Conniventes or the Valves of Kekring (plicae circulares [Kerkringi]) (Fig. 897) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue; they contain no muscular fibres, and, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once around the bowel, but occasionally two or three times. The spiral arrangement is the characteristic one of the shark family of fishes. The larger folds are about one-third of an inch in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they
are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulae conniventes retard the passage of the food along the intestine, and afford a more extensive surface for absorption.

The villi (villi intestinales) (Figs. 896, 898, 899, 900, and 905) are minute, highly vascular processes, never larger than one millimetre, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They spring from the valvulae conniventes and also from the spaces between them. In shape, according to Rauber, they are short and leaf-shaped in the duodenum, tongue-shaped in the jejunum, and filiform in the ileum. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

Structure of the Villi (Figs. 899 and 900).—The structure of the villi has been studied by many eminent anatomists. We shall here follow the description of Watney, whose researches have a most important bearing on the physiology of that which is the peculiar function of this part of the intestine, the absorption of fat.

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the epithelium, the basement-membrane and muscular tissue of the mucous, these structures being supported and held together by retiform lymphoid tissue.

---

**Fig. 898.—Mucosa of small intestine in ideal vertical cross-section. (Testut, after Heitzmann.)**

Philip. Trans., vol. clxv. part ii.
**Fig. 899.**—Diagrammatic section of a villus. *ep.* Epithelium only partially shaded in. *l.* Central chyle-vessel; the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m.* Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e,* or to the reticulum of the villus. *lc.* Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *e′,* *e,* *e′.* Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the upper part of the chyle-vessel, and the cells of the membrana propria. *v.* Blood-vessels. *z.* Dark line at base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or "nodal points." The diagram shows that the cells of the upper part of the chyle-vessel differ somewhat from those of the lower part in that they more nearly resemble the cells of the parenchyma. (Watney.)

**Fig. 900.**—Villi of small intestine. (Cadiat.)
These structures are arranged in the following manner: situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity; running along this vessel are unstriped muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement-membrane, and covered by columnar epithelium. Those structures which are contained within the basement-membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large, flattened cells with oval nuclei, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behavior with reagents, by their size, and by the shape of the nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscles and the proper cells of the villus. Nerve-fibres are contained within the villi; they form ramifications throughout the reticulum.

The lacteals are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated caecal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

The muscular fibres are derived from the muscularis mucosae, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane.

The blood-vessels form a plexus between the lacteal and the basement-membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement-membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement-membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar epithelial cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that the chyle passes in the process of absorption by the villi; that is to say, it passes first of all into the colunmnar

**Fig. 901.—Section of a gland of Lieberkühn in the mouse. (Paneth.)**

**Fig. 902.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)**
epithelial cells, and, escaping from them, is carried into the reticulum of the villus, and thence into the central lacteal.

The Simple Follicles, Intestinal Glands, Crypts or Glands of Lieberkühn (glandulae intestinales [Lieberkuhni]) (Figs. 901, 902, and 905) are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi (Fig. 896). Their walls are thin, consisting of a basement-membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The Duodenal or Brunner's Glands (glandulae duodenales [Brunneri]) are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies embedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They are small, compound, acino-tubular glands, and much resemble the small glands which are found in the mucous membrane of the mouth. They are believed by Watney to be direct continuations of the pyloric glands of the stomach. They consist of a number of tubular alveoli, lined by epithelium, and opening by a single duct on the inner surface of the intestine.

The Lymph Nodules (noduli lymphatici) are small pyriform structures. The bodies of the nodes are in the submucous coat; the apices are in the mucous membrane, which is thrown by them into rounded elevations. They are divided into solitary glands and Peyer's glands.

The solitary glands (noduli lymphatici solitarii) (Figs. 896 and 898) are found scattered throughout the mucous membrane of the small intestine and the large intestine. In the small intestine they are most numerous in the lower part of the ileum, upon and between the valvulae conniventes. They are small, round, whitish bodies, from one-twenty-fourth of an inch to one-quarter of an inch in diameter. Their free surface is covered with villi, and each gland is surrounded by the
openings of the follicles of Lieberkühn. They are now recognized as lymph-nodules. They consist of a dense interlacing retiform tissue closely packed with lymph-corpuscles and permeated with an abundant capillary network. The inter-spaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, whence they form slight projections of its epithelial layer, after having penetrated the muscularis mucosae. The villi situated on them are generally absent from the very summit (or "cupola," as Frey calls it) of the gland.

Peyer's glands, Peyer's patches, the agminated glands or the tonsillae intestinales (noduli lymphatici aggregati [Peyeri]) (Figs. 903, 904, and 905) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty-five to forty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated

![Diagram of Peyer's patch](image)

Fig. 905.—Vertical cell of a Peyer's patch in a man with the lymphatic vessels injected. (Frey.)

in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life. They are largely supplied with blood-vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are found throughout the small intestine are especially abundant around these patches; here they form rich plexuses with sinuses around the glands (Fig. 905). In typhoid fever there is ulceration of Peyer's patches.

Vessels and Nerves.—The arteriae (vasa intestini tenuis) are branches of the superior mesenteric (Fig. 420) and ascend within the mesentery, forming single, double, or even tertiary loops (Figs. 869, 870, 871, 872, 873, 874, and 906). The terminal branches reach the intestine, and each branch divides into two, one going to each side of the intestine and passing transversely around it. At first they are
directly beneath the peritoneum, but after a time they pass to the submucosa and form a plexus, from which branches go to the mucous membrane. Some of these enter the villi; others form plexuses about the glands of Lieberkühn (Birmingham).

![A loop of small intestine, showing the mode of distribution of the arteries. (Testut.)](image)

Dr. George H. Monks¹ points out that opposite the upper portion of the bowel the mesenteric vessels form only primary loops; as we pass down secondary loops appear, become larger and more and more numerous, and actually prominent features about the fourth foot. As we descend the secondary loops become larger and more numerous and the primary become smaller. All the time the loops get nearer and nearer to the bowel. Tertiary loops may appear. Opposite the lower part of the ileum the loops cease to be characteristic and they form a network. (Monks's views are fully set forth on pp. 1266, 1267, and 1268.) In the upper part of the gut the vasa recta are from 3 to 5 cm. long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than 1 cm. in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery.

The veins correspond to the arteries, and the venous blood passes to the superior mesenteric vein, which, it will be remembered, unites with the splenic vein to form the portal vein. The mesenteric veins are devoid of valves.

The lacteals are lymphatics (Figs. 898, 899, 900, and 905) which arise in the villi. Lymphatics also begin in sinuses at the base of the solitary glands and as lymph-nodes in the submucous coat. Peyer's patches are aggregations of lymph-nodes. There is an extensive lymphatic plexus in the submucous coat, another in the muscular coat, another under the peritoneum. The submucous plexus is formed by lymphatics from the villi and mucous membrane. This plexus is joined by lymphatics from the bases of the solitary glands, and the lymph passes by vessels to larger vessels at the mesenteric border of the gut. The muscular lymphatics are placed between the two muscular layers. They

¹ Annals of Surgery, May, 1903.
form a plexus and communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement

Fig. 908.—Meissner's plexus.

Fig. 909.—Meissner's plexus. (Klein and Noble Smith.)
The large intestine extends from the termination of the ileum to the anus. It is about five feet or more in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the caecum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. The diameter of the distended caecum is usually about three inches; the diameter of the descending colon is about one and a half inches. The large intestine differs from the small intestine in its greater size, its more fixed position, its sacculated form (Figs. 910 and 911), and in possessing certain appendages to its external coat, the appendices epiploicae (Fig. 910). The appendices epiploicae are peritoneal pouches containing fat, unless the subject is greatly wasted; they protrude here and there from the peritoneal coat of the entire large bowel, except the rectum, and are particularly frequent along the anterior longi-

Fig. 910.—Large intestine. A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—sacculation, taeniae and appendices epiploicae—are shown. (Cunningham.)

Fig. 911.—Segment of large intestine, showing the characteristic features of its structure. (Testut.)
tudinal band. Further, the longitudinal muscular fibres of the large intestine do not form a continuous layer around the gut, but are arranged in three longitudinal bands or taeniae (taeniae coli) (Fig. 911). The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the caecum. It ascends through the right lumbar and right hypochondriac regions to the under surface of the liver; it here takes a bend to the left, the hepatic flexure, and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again, the splenic flexure, and descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the sigmoid flexure; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the caecum, colon, and rectum.

The Caecum (Intestinum Caecum) (Figs. 912, 913).

The caecum, the commencement of the large intestine, is the large blind pouch, or cul-de-sac, situated below the ileo-caecal valve. Its name is derived from caecus, blind. Its blind end or fundus is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name capitum caecum coli was applied to it. An incomplete groove marks the upper limit of the caecum. This groove is at the level of the opening of the ileum. When the caecum is contracted it bends on this groove as on a hinge and forms an angle with the ascending colon. In the contracted caecum sacculations are but slightly evident; in the distended caecum they are definite. Its size is variously estimated by different authors, but on an average it may be said to be two and a half inches in length and three in breadth. In 435 careful autopsies, Byron Robinson found the caecum and appendix congenitally absent in one case. The same author says that excessively large caeca are found in a little less than one-third of all autopsies. A large caecum may be four inches in width, entirely surrounded by peritoneum and usually is excessively mobile. Sometimes an excessively small caecum is encountered. According to Byron Robinson, this results from diminution of the blood-supply during the axial rotation and caecal descent of development. An adult caecum may be only one inch in width and one-half an inch in length, and it is usually devoid of mobility. It is situated in the right iliac fossa, above the outer half of Poupart's ligament, usually rests on the Ilio-psosas muscle, the iliac fascia intervening, and lies immediately behind the abdominal wall. The right side of the caecum is in contact with the outer wall of the abdomen, and the outer aspect of the anterior wall of the caecum is in contact with the anterior abdominal wall (Spalteholz). When the caecum is full the small intestine lies in front of the left

1 St. Louis Courier of Medicine, October–December, 1902.
side and lower portion of the anterior caecal wall. If the caecum is empty the small intestine lies in front of its anterior wall, and the lower end is on a higher level than when this portion of the gut is full. In 15 per cent. of cases the caecum is covered by the omentum (Byron Robinson). Byron Robinson describes four positions of the caecum: 1. On the Psoas muscle. 2. To the right of the Psoas muscle. 3. In the pelvis. 4. The potential position, in which it lies free in the abdominal cavity. It may be found in various positions in the abdomen, because of elongation of the fixation apparatus. The commonest position is on the Psoas muscle, and this position is even more common in men than in women. It is twice as often in the pelvis in women as in men—20 per cent. of cases in the former; 10 per cent. in the latter. As a rule, it is entirely enveloped on all sides by peritoneum, but in a certain number of cases (6 per cent., according to Berry) the peritoneal covering is not complete, so that a small portion of the upper end of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. As a matter of fact, there is no real mesocaecum—meaning by the term a peritoneal fold which holds the caecum to the dorsal wall of the abdomen—except when there is failure in development. The normal caecum is completely invested by peritoneum from the beginning. Originally the caecum receives its blood along a single peritoneal fold, the ileo-caecal fold, which is a simple mesentery. As development advances, this simple mesentery becomes a double fold and practically bloodless, and is replaced by two vascular folds, the mesappendix to the left and the mesenterico-colicum to the right. The mobility of the caecum varies. Very small caeca are fixed. In most cases the caecum lies quite free in the abdominal cavity and enjoys a considerable amount of movement. Sometimes it is excessively mobile, and in such cases is usually also of large size. Such mobility is due to a stretched fixation apparatus. A very large and mobile caecum may be made to come in contact with any abdominal viscera and may enter any hernial sac on either side. As a rule, when the caecum is large and mobile, it is found in the pelvis or in the middle of the abdomen (Byron Robinson). It is to be remembered that a mobile caecum carrying with it the appendix may pass to almost any region of the abdomen. Sometimes the caecum fails to descend or only descends a part of the way during development, the axial rotation of the intestinal tract having been arrested. In such a case it may terminate at the level of the gall-bladder, and the ascending colon is absent. In 310 adult males Byron Robinson found 8 per cent. with undescented caecum and appendix. Non-descent is found in less than 4 per cent. of adult females. A partly descended caecum usually lies upon the right kidney.

The caecum varies in shape, but, according to Treves, in man it may be classified under one of four types (Fig. 913). In early foetal life it is short, conical, and broad at the base, with its apex turned upward and inward toward the ileo-caecal junction. It then resembles the caecum of some of the monkey tribe, e. g., Mangabey monkey. As the foetus grows the caecum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inward of the apex toward the ileo-caecal junction. This form is seen in others of the monkey tribe, e. g., the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the veriform appendix, hanging from a conical projection, the caecum. This is the infantile form, and as it persists throughout life, in about 2 per cent. of cases, it is regarded by Treves as the first of his four types of human caeca. The caecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the second type, the conical caecum has become quadrate by the growing out of a saccele on either side of the anterior longitudinal band. These sacceles are of equal size,
and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The third type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right saccule, and the original apex, with the appendix attached, is pushed over to the left toward the ileo-caecal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and postero-external bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The fourth type is merely an exaggerated condition of the third;

![Diagram of four types of caecum](image)

Fig. 913.—The four types of caecum.

the right saccule is still larger, and at the same time the left saccule has been atrophied, so that the original apex of the caecum, with the appendix, is close to the ileo-caecal junction, and the anterior band courses inward to the same situation. This type is present in about 4 per cent. of cases.

Supports of the Caecum.—According to Byron Robinson, the caecum is maintained in position by the mesocolon and a peritoneal fold, the right phrenico-colic ligament, which arises from the hepato-duodenal and hepato-renal ligaments. It receives support from the connective tissue about vessels and nerves, and inconstantly from folds which fixes it in the iliac fossa and in the region of the vena cava.

---

1 St. Louis Courier of Medicine, October-December, 1902.
The Interior of the Caecum.—In the interior of the caecum are seen depressions which correspond to the surface 
haustra, and semilunar folds (plicae semilunares coli) (Fig. 912), which correspond to the transverse surface constrictions. There are three openings in the caecum: that into the colon; that into the ileum, which is guarded by the ileo-caecal valve (p. 1305); and that into the appendix, which may be guarded by the valve of Gerlach. 

Pericaecal Folds and Fossae.—See p. 1262, and Figs. 866, 867, and 868. 

The Vermiform Appendix (processus vermiciformis) (Figs. 866, 867, 868, 913, 914, 915, 916, and 918).—The vermiform appendix is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the caecum is very slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous caecum, which has been replaced by the carnivorous form.\(^1\) The vermiform appendix is a long, narrow, worm-shaped, musculo-membranous tube, which starts from what was originally the apex of the caecum. After development has advanced the vermiform appendix comes off, as a rule, from the inner side of the posterior wall of the caecum that is below and behind the termination of the ileum. This origin usually corresponds to McBurney's point, which is in the abdominal wall, midway between the umbilicus and the anterior superior iliac spine and which is the usual seat of the greatest tenderness in appendicitis. The origin of the appendix varies with the type of caecum present. These variations are shown in Fig. 913. In the foetal or infantile type of appendix it arises from the apex of the caecum; in the second type of caecum it arises between the two caecal sacculi; in the third type it arises between a large outer and a small inner sacculus; and on the posterior wall of the caecum, the excessive growth of the anterior wall having caused the appendix to originate posteriorly; in the fourth type there is no internal sacculus, and the appendix arises from the posterior caecal wall behind the ileo-caecal junction (p. 1302). The movable portion of the appendix may be met with in different situations. It may pass upward and in front of the caecum and colon, upward and behind the caecum, and even behind the colon between the two layers of the mesocolon; upward and to the inner side, or upward and to the outer side of the caecum and colon. It may pass to the left under the ileum and mesentery, upward and to the left or downward and to the left into the true pelvis. It may pass directly downward under the caecum. It may pass to the right in front of or back of the caecum. It may occupy any one of the caecal fossae (p. 1262), but most often enters the ileo-caecal fossa. In unusual cases the appendix is found in the inguinal canal as a portion of or the sole contents of a hernia; adherent to the parietal peritoneum in front of or to the side of the caecum, or “behind the peritoneum, below the caecum, adherent to the under surface of the caecum and in contact with its muscular wall and covered by its peritoneal coat.”\(^2\) When the caecum is mobile the appendix may be found almost anywhere within the abdomen. When the caecum is undescended the appendix, of course, shares in the failure to descend, and may be below the gall-bladder or in front of the right kidney, and may pass in several directions: upward behind the caecum; to the left behind the ileum and mesentery; or downward and inward into the true pelvis. It varies from one-half an inch to nine inches in length, its average being about three inches. Its diameter is from one-eighth inch to one-quarter inch. The operating surgeon may occasionally fail to find an appendix buried in one of the caecal fossae, and may conclude that the diverticulum is absent. As a matter of fact, unless the colon is also absent, it seems doubtful if the appendix is ever absent, except as a result of dis-

---

\(^1\) Cunningham's Text-book of Anatomy.

\(^2\) Deaver's Surgical Anatomy.
ease. This view is maintained by Lockwood and Rolleston,1 by Kelynack,2 and others. It is asserted by some that the appendix is absent five times out of 10,000 autopsies. It is retained in position by a fold of peritoneum derived from the left leaf of the mesentery, which forms a mesentery for it, and is called the meso-
appendix (p. 1260, and Figs. 866, 867, and 868). In color the healthy appendix is yellowish-pink, is soft and smooth to the touch, and the "subperitoneal vessels are barely visible."3 The canal of the appendix is small and extends throughout the whole length of the tube. The walls of the healthy diverticulum are thick, and the diameter of the lumen is usually trivial as compared with the diameter of the appendix itself. The lumen of the appendix communicates with the caecum by an orifice which is placed below and behind the ileo-caecal opening (Fig. 919). It is sometimes guarded above and to the left side by a semilunar fold of mucous membrane, the valve of Gerlach (valvula processus vermiciformis). The valve is inconstant, and is never perfect. It is stated that the appendix tends to undergo obliteration as an involution change in a functionless organ. The lumen rarely contains foreign bodies after death, but often contains fecal concretions. Certain it is that in 25 per cent. of necropsies upon adults or elderly people the lumen is found to be partially or completely occluded.

Structure of the Appendix (Fig. 917).—The coats of the appendix correspond to the coats of the bowel: serous, muscular (the outer layer of longitudinal, the inner of circular fibres), submucous, and mucous. In the deepest portion of the mucous coat, against the submucous coat, are the unstriated fibres constituting the muscularis mucosae. The muscularis mucosae is often present in some regions and absent in others. It may not be present at all.

The Outer or Serous Coat usually completely covers the appendix and has a definite mesentery, the mesoappendix (p. 1260). Occasionally the base of the appendix is not surrounded by peritoneum, but is extraperitoneal, lying in the retroperitoneal tissue. The appendiculo-ovarian ligament of Clado is occasionally present in females. It is a prolongation of the mesoappendix which passes into the broad ligament, and is extremely thin, and its fine connective-tissue fibres send prolongations into the longitudinal muscle-fibres of the appendix. Lockwood points out that the subperitoneal tissue of the meso-appendix and "the blood-vessels, nerves, and lymphatics which it contains are very intimately connected with the submucosa. This union takes place at certain large gaps in the muscular coats. These gaps serve for the transmission of blood-vessels, nerves,

2 A Contribution to the Pathology of the Vermiform Appendix.
3 Lockwood on Appendicitis.
and lymphatics from the mesoappendix to the mucous coat. They are situated at the junction of the mesoappendix with the appendix."

The Longitudinal Muscular Layer is thin and irregularly distributed, and in certain regions may be excessively thin or actually absent, and between the fibres are the blood-vessels, nerves, and lymphatics passing from the subperitoneal tissue to the mucous coat.

The Circular Fibres are much better developed than the longitudinal fibres, and, according to Lockwood, the layer is 1 mm. thick. Large gaps are found here and there for the passage of vessels, lymphatics, and nerves to and from the meso-appendix and the mucous membrane, and a few vessels pierce the fibres at other points (Lockwood).

The Submucous Coat varies greatly in thickness. It contains blood-vessels, nerves, and lymphatics, and some lymphoid follicles.

The Mucous Membrane (Fig. 915) is covered by columnar epithelial cells and contains numerous solitary lymph-follicles, some glands of Lieberkühn, surrounded by lymphoid tissue, blood-vessels, lymphatics, and nerves.

The muscularis mucosae may be absent, may be scanty or may be distinct. The lymphoid follicles are visible to the naked eye (Fig. 915). Some of them are in the submucosa, some of them chiefly in the mucosa, the bases of the latter, however, being in the submucosa. Lockwood estimates that an appendix three and a half inches in length contains from 150 to 200 follicles.

Blood-vessels of the Caecum and Appendix (Figs. 914, 916, 932, and 933).—The ileo-colic artery in the ileo-colic angle gives off the anterior and posterior ileo-caecal arteries. The anterior ileo-caecal runs down over the front of the ileum and supplies the ileum, and sends off a terminal branch, the anterior caecal artery, which supplies the anterior surface of the caecum and of a portion of the ascending colon, and to the upper and lower margins of the ileo-caecal valve. It sends no branch to the appendix. The arteries of the appendix come from the posterior ileo-caecal artery. This vessel, after arising from the ileo-colic artery, passes back of the termination of the ileum and gives branches to the lower end of the ileum back of a portion of the ascending colon and to the lower margin of the ileo-caecal valve, where they anastomose with the valvular branches from the anterior ileo-caecal (Lockwood). From the posterior ileo-caecal comes the posterior caecal branch, which passes over the posterior and inner portion of the caecum near the base of the appendix and sends one or two branches to the appendix. The chief blood-supply of the appendix is the appendicular artery, which comes off the beginning of the posterior ileo-caecal or, occasionally, from the termination of the ileo-colic. If there is a distinct mesoappendix the largest branch of the artery passes along its free edge. If the mesoappendix is absent or rudimentary the artery usually lies upon the appendix from base to tip beneath the peritoneum.

Lockwood points out that the appendicular artery as it enters the mesoappendix divides into three branches. The largest branch runs along the free edge, and from this the tip of the appendix obtains its blood-supply; "the other two reach the appendix at intervals of half an inch." When the branches reach the appendix they divide and pass around it in the subperitoneal coat and send

---

2 Ibid.
branches through the muscular gaps to enter and pass through the submucous coat.

In females there is occasionally some additional blood-supply through a branch of the ovarian artery in the appendiculo-ovarian ligament.

The veins of the appendix are numerous, thin walled, and large. Veins from the submucous plexus pass through the muscular gaps and enter the subperitoneal plexus. Veins from the subperitoneal plexus pass into veins in the mesoappendix which correspond to but do not really accompany the arteries (Lockwood). Most of the veins of the mesoappendix pass to the posterior ileo-caecal vein, though some pass directly to the caecal vein. These veins are radicles of the portal system.

**Lymphatic System of the Caecum and Appendix** (Fig. 918).—Surrounding the base of each lymph-follicle in the submucous tissue of the appendix is a lymph-space, which Lockwood calls the follicular or basilar lymph-sinus. This sinus communicates with the lymphatics of the submucous coat, “which again communicate freely through the hiatus muscularis with those of the peritoneum and of the mesoappendix.”\(^1\) The collecting trunks from the caecum and appendix follow the

---

\(^{1}\) Appendicitis, its Pathology and Surgery. By Charles Barrett Lockwood.
blood-vessels (Fig. 918). The anterior collecting trunks of the caecum pass through several small glands in the anterior ileo-caecal fold, and terminate in glands along the ileo-colic artery (Fig. 918). The posterior collecting trunks pass through some small glands and terminate in glands along the ileo-colic artery. The appendicular collecting trunks enter the mesoappendix. There are usually four of them, sometimes five. Some of them traverse a gland constantly present at the ileo-caecal angle (Clado). Another gland is constant. It is situated beneath the ileo-colic fossa (Lockwood and Rolleston). The editor subscribes to Lockwood's statement that in appendicitis there is often a chain of inflamed glands along the inner side of the ascending colon behind the
ascending mesocolon. Hence this is one road taken by the lymphatics of the appendix. The others pass to the mesenteric glands.

The Ileo-caecal Valve or the Valve of Bauhin (valvula coli) (Figs. 919, 920, 921, and 922).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the caecum with the colon. The opening is guarded by a valve, consisting of two semilunar segments, an upper or colic segment (labium superius) and a lower or caecal segment (labium inferius), which project into the lumen of the large intestine. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, which is more concave and longer, is attached to the point of junction of the ileum with the caecum. At each end of the aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge around the canal for a short distance. Each ridge is known as the retinaculum or frenulum of the valve (frenulum valvulae coli). The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the formation of the valve the termination of the small intestine invaginates for a short distance into the lumen of the large intestine (Fig. 920), the invaginated portion of the wall of the small intestine uniting with a corresponding portion of the wall of the large intestine.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one portion of the intestine to the other. When the longitudinal fibres and peritoneum are divided or removed, the ileum may be drawn outward, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed toward the ileum possesses villi, and presents the characteristic structure of the mucous membrane of the small intestine; while that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue
as far as the free margins of the valve. When the caecum is distended it is supposed that the margins of the opening are approximated so as to prevent reflux into the ileum. It is known, however, that a very large enema which distends the caecum and colon may in part enter the ileum, being driven there by waves of reversed peristalsis. The valve resists, but a certain amount of pressure overcomes it. Some believe that the so-called ileo-caecal valve is not a valve, but a distinct sphincter. This has been demonstrated to be true in cats and dogs, but lacks demonstration in man (p. 1323).

The Colon.

The colon is divided into four parts—the ascending, transverse and descending colon, and the sigmoid flexure.

The Ascending Colon (colon ascendens).—The ascending colon is smaller than the caecum, with which it is continuous. It passes upward, from its commencement at the frenula of the caecum, opposite the ileo-caecal valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression on the liver, the impressio colica; here it bends abruptly inward to the left, forming the hepatic flexure (flexura coli dextra). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum and Transversalis muscles, and with the front of the lower and outer part of the right kidney (Fig. 923). Sometimes the peritoneum almost completely invests it, and forms a distinct but short mesocolon1 (p. 1259). It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The Transverse Colon (colon transversum) (Fig. 858).—The transverse colon, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward beneath the lower end of the spleen, forming the splenic flexure (flexura coli sinistra). In its course the transverse colon describes an arch, the concavity of which is directed backward toward the vertebral column and a little upward; hence the name transverse arch of the colon. This is the most movable part of the colon, being almost completely invested by peritoneum, and connected to the spine behind by a large and wide duplicature of that membrane, the transverse mesocolon (Fig. 863). The transverse colon is in relation, by its upper surface with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; its posterior surface on the right side is in relation with the second portion of the duodenum, and on the left side is in contact with some of the convolutions of the jejunum and ileum.

The Descending Colon (colon descendens).—The descending colon passes downward through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns inward toward the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the sigmoid flexure. At its commencement it is connected with the Diaphragm by a fold of peritoneum, the phrenico-colic ligament (see p. 1259). It is retained in position by the peritoneum, which covers its

1 Treves states that after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colostomy a mesocolon may be expected on the left side in 36 per cent. of all cases, and on the right in 26 per cent. (The Anatomy of the Intestinal Canal and Peritoneum in Man. 1885, p. 55.)—Ed. of 15th English edition.
anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and the Quadratus lumborum and

Transversalis muscles (Fig. 863). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).
The Sigmoid Flexure, Pelvic Colon or Sigmoid Colon (colon sigmoideum) (Figs. 924, 925, 926, and 927) is the narrowest part of the colon; it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the margin of the crest of the ilium, and then forming a loop, which varies in length and position, and which terminates in the rectum at the level of the attachment of the mesentery upon the front of the third sacral vertebra. It passes downward about two inches parallel to the outer border of the Psoas muscle, then taking a transverse direction enters the cavity of the pelvis, crosses this cavity from left to right and a little upward to the lower margin of the right iliac fossa; "from this point it passes downward, backward, and inward along the anterior surface of the sacrum to its junction with the rectum." It is surrounded with the peritoneum and is attached to the poste-

rior abdominal wall by the mesosigmoid, a continuation of the mesocolon, but which greatly exceeds the latter in length, hence the sigmoid is the most mobile

1 Tuttle, Diseases of the Anus, Rectum, and Pelvic Colon.
portion of the large intestine. Tuttle divides the sigmoid into four portions. The first or vertical portion; the second or transverse portion; the third portion, which is a loop and is concave upward if the sigmoid occupies the pelvis, and is concave downward if it occupies the abdomen; the fourth portion, which is curved irregularly in the hollow of the sacrum, and which joins the rectum as often from the right as from the left. When the sigmoid is lifted up and to the right and the mesosigmoid is put slightly upon the stretch, an opening is seen at the parietal border of the left layer of the mesosigmoid. This opening leads into a cul-de-sac, the intersigmoid fossa. When the sigmoid is empty most of it falls into the recto-vesical or recto-vaginal space (Fig. 925). When distended it mounts up into the abdomen, reaching to or even above the umbilicus. The sigmoid flexure is in relation in front with the small intestine and abdominal parietes. The sigmoid mesocolon is attached to a line running downward and inward from the crest of the ilium, across the Psoas muscle (Fig. 863).

The Rectum (Intestinum Rectum) (Figs. 924, 925, 926, 927, 928, 929).

The rectum is the terminal part of the large intestine, and extends from the termination of the sigmoid flexure to the level of the semilunar valves of Mor-gagni. The sigmoid flexure terminates at the level of the attachment of the mesentery in front of the third sacral vertebra. This definition is practical and useful. It was suggested by Sir Frederick Treves. "It gives to the organ definite limits; it separates the mobile from the immobile portion of the gut; it marks the line where the course of the blood-supply changes; it indicates the
point where the three longitudinal muscular bands of the colon spread out and become more or less equally distributed around the gut; and, finally, it marks a point at which there is always a decided narrowing in calibre, indicating the juncture of the rectum with the pelvic colon." The old division added to this the so-called first part of the rectum, which we consider as part of the sigmoid colon. The rectum is divided into two portions, a superior and an inferior. The superior or sacrococcygeal portion of the rectum (flexura sacralis) curves downward with the concavity forward and upward in front of the sacrum and coccyx, and is continued as far as the apex of the prostate gland, about an inch in front of the tip of the coccyx. The inferior or prostatic portion (flexura perinealis) begins at this point. The bowel is directed downward and backward, being convex in front, and terminates at the beginning of the anus at the level of the semilunar valves of Morgagni. The inferior or prostatic portion of the rectum is described by Symington as the anal canal.

Curves of the Rectum.—It will be seen, therefore, that the rectum presents two antero-posterior curves: the first, with its convexity backward, is due to the conformation of the sacro-coccygeal column, and represents the arc of a circle, the centre of which is opposite the third sacral vertebra. The lower one has its convexity forward, and is angular. Its centre corresponds to a line drawn between the anterior parts of the ischial tuberosities. Two lateral curves are also described: the one to the right, opposite the junction of the third and fourth sacral vertebrae; the other to the left, opposite the sacro-coccygeal articulation. They are of little importance.

The adult rectum as here described has a length of from four to six inches in men, and from three and five-eighths to five and one-eighth inches in women. According to Tuttle the length of the rectum depends to some degree on the size of the

---

1 A Treatise on Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle.
subject, and is somewhat greater in the old than in the young. The prostatic portion is the narrowest portion of the rectum. The widest part of the rectum is the \textit{ampulla recti} just above the anal canal (Figs. 926 and 927). The prostatic portion has no peritoneal investment whatever and includes the lower two inches of the superior portion of the rectum. When the rectum is empty it is a mere slit, the anterior and posterior walls being in contact. When distended it is "irregularly cylindrical" (Tuttle). At and above the level of the third sacral vertebra the gut is entirely surrounded by peritoneum, and there is a mesosigmoid. This is the mesorectum of those who describe the lower pelvic colon as the first part of the rectum. At the level of the third sacral vertebra the true rectum begins, and the true rectum has no mesorectum. The rectum is covered in front and laterally by peritoneum at its upper part; gradually the peritoneum leaves its sides, and about an inch above the prostate is reflected from the anterior surface of the bowel on to the posterior wall of the bladder in the male, and the upper fifth of the posterior wall of the vagina in the female, forming the \textit{recto-vesical} or \textit{recto-vaginal pouch} (excavatio rectovesicalis and excavatio rectovagina), as the case may be (Fig. 853). The balance of the rectum has no peritoneal covering. The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the rectovesical pouch is about three inches; that is to say, the height to which an ordinary index finger can reach from the anus. In the female the height of the recto-vaginal pouch is about two and a quarter inches from the anal orifice.

The upper or sacro-coccygeal portion of the rectum is in relation, in front, in the male, with the recto-vesical pouch, the triangular portion of the base of the bladder, the vesiculae seminales, and vasa deferentia, and more anteriorly with the under surface of the prostate. In the female, with the posterior wall of the vagina below, and the recto-vaginal pouch above, in which are some convolutions of the small intestine (Fig. 927). To the sides below the peritoneal reflections, the rectum is surrounded by cellular tissue in which on each side lie the lateral sacral artery and the bifurcated hypogastric plexus. This portion of the rectum is separated from the sacrum and coccyx by an interval, the \textit{retrorectal space}, which is filled with cellular tissue. The superior portion of the distended rectum is in contact posteriorly and on each side with the sacral plexus, ganglia of the sympathetic, and the fascial origin of the pyramidalis muscle (Tuttle). The lower or prostatic portion in men is in relation anteriorly with the prostate gland and the membranous urethra; in women with the posterior wall of the vagina. The lower end of the rectum takes a backward turn, and the uro-genital organs turn forward; the intervening space is called the \textit{perineum}. In the female, the fibro-fatty and muscular tissue which occupies this space is called the \textit{perineal body}. The prostatic portion of the rectum is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter; in the empty condition it presents the appearance of a longitudinal slit. Posteriorly the lower part of the rectum is in contact with cellular tissue, which separates it from the coccygeal gland and the coccyx.
Supports of the Rectum.—The rectum as it has been described in these pages is a fixed tube. The upper portion of the rectum is supported by “the inferior mesenteric arteries and the fibrous sheaths which surround them” (Tuttle); by the peritoneal folds which attach it to the sacrum; and by the peritoneal folds which pass in front to the bladder (plicae rectovesicales), or to the uterus (plicae rectouterinae), and laterally to the pelvis. The middle of the rectum receives some support from the lateral sacral arteries and their fibrous sheaths. The lower portion of the rectum is supported by the Levator ani, External sphincter, and Recto-coccygeus muscles.

Blood-vessels and Lymphatics of Rectum.—See pp. 1320 and 1322.

Nerves of Rectum.—See p. 1322.

Structure of Rectum.—See p. 1316.

The Common Anal Canal (pars analis recti) (Figs. 929 and 930).—The anal canal is the third portion of the rectum of the older descriptions. It begins where the true rectum ends. This canal is the portion of the intestinal tract which is below the distribution of genuine mucous membrane, and is just posterior to the middle of a line drawn from one tuberosity to the other. It lies between the true skin and the upper borders of the semilunar valves of Morgagni. When at rest it is a mere slit placed antero-posteriorly. The external opening of the anal canal is the anus. The skin about the anus is pigmented, is thrown into radiating folds by the contraction of the External sphincter muscle, and contains hairs, sebaceous glands, and sudoriparous glands (glandulae circumanales). Ascending into the canal, it alters its character and becomes muco-cutaneous,
and true mucous membrane appears at the rectum proper. Back of the anus is a median cutaneous fold passing posterior to the coccyx and called the anal raphé. In front of the anus is a median fold which, in the female, passes forward and merges with the labia major and in the male continues into the raphé of the scrotum. This is called the perineal raphé. The length of the anal canal is three-quarters to one inch. "Its circumference varies from 3 cm. (one and three-sixteenths inches) in normal condition to 15 cm. (five and five-sixteenths inches) in disease, following injury or vicious practices. The average anus will admit a cylinder of 65 mm. in circumference without rupturing the mucous membrane."

**Relations of the Anal Canal.**—It is surrounded by the external and internal sphincter muscles, and above by the Levatores ani. To each side is the ischio-rectal fossa containing fat. Between the anal canal and the coccyx is a collection of muscular fibres and connective tissue, the ano-coccygeal body of Symington. In front, in the male, is the bulb of the urethra and the base of the triangular ligament; in the female, is the perineal body, which separates the anus from the vagina. There are three layers in the wall of the anal canal:

1. The **mucous-cutaneous layer**, which contains glands, blood-vessels, and numerous nerve-endings. The lower portion is covered with pavement-epithelium, but gradually there is a transition, and at the beginning of the rectum proper the epithelium is entirely columnar. The valves of Morgagni, the anal valves or the semilunar valves (Figs. 930 and 931) are in the upper portion of the anal canal between the lower ends of the columns of Morgagni (Figs. 930 and 931). Above the valves the canal is lined by transitional mucous membrane, below them by modified skin.

The ano-rectal line is not straight, but is irregularly dentated by trivial elevations, each of which is papilliform at its summit. According to Tuttle, these elevations number from five to eight. About one-fifth of an inch below the ano-rectal line is the depression known as Hilton's white line (annulus haemorrhoidalis) (Fig. 931). This line is somewhat indistinct to sight, but can always be felt with the finger. It marks the junction of the External with the Internal sphincter. Above Hilton's line are some mucous crypts and also dilatations produced by the internal haemorrhoidal plexus of veins (Fig. 931).

2. The **fibro-cellular layer** is beneath the mucous membrane. Above Hilton's line it is composed of cellular tissue; below it is a thin fascia-like layer which joins the superficial fascia.

The anal canal is surrounded by longitudinal fibres from the rectum, fibres from the Levator ani, the lower portion of the Internal sphincter, and particularly by the External sphincter.

**Blood-vessels, Lymphatics, and Nerves of Anus.**—See pp. 1321 and 1322.

**Structure of Large Intestine (including the Rectum and Anal Canal).**—The large intestine has four coats—serous, muscular, areolar or submucous and mucous.

The **Serous Coat** (tunica serosa).—The serous coat is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The caecum is completely covered by the serous membrane, except in a small percentage of cases (5 or 6 per cent.), where a small portion of the upper end of the posterior surface is uncovered. The ascending and descending colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered. The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The sigmoid flexure is completely surrounded, except along the line to which the sigmoid mesocolon is attached. The upper two-thirds of the rectum is covered in front and laterally by the peritoneum, but not posteriorly, between the two posterior folds of peritoneum, the so-called mesorectum; later

---

it is covered only on its anterior surface; and the lower portion is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicae*. They are chiefly appended to the transverse colon, and are particularly numerous along the anterior band.

The **Muscular Coat** (*tunica muscularis*).—The muscular coat consists of an **external longitudinal** and an **internal circular layer** of muscular fibres.

The **Longitudinal Fibres**, although found to a certain extent all around the intestine, do not form a uniform layer over the whole surface of the large intestine. In the caecum and colon they are especially collected into three flat **longitudinal bands** or **taeniae** (*taeniae coli*) (Figs. 910 and 911), each being about half an inch in width. These bands commence at the base of the vermiform appendix, which structure is surrounded by a uniform layer of longitudinal muscular fibres. The bands pass from the base of the appendix to the rectum. At this point they broaden, fuse, and surround the rectum. On the ascending, descending, and sigmoid colon the **mesocolic band** (*taenia mesocolica*) is posterior and internal; the **omental band** (*taenia omentalis*) is posterior and external; the **free band** (*taenia libera*) is anterior. On the transverse colon the *taenia* *libera* is inferior; the *taenia mesocolica* is posterior; the *taenia omentalis* is anterior and superior. These bands are one-sixth shorter than the other coats of the intestine to which they are applied, and serve to produce the **sacculi** (Fig. 911), which are characteristic of the caecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. The sacculations are called *haustra coli*. There are three rows of the sacculations separated from each other by the longitudinal bands. These pouches are also subdivided by transverse furrows which correspond to con cave folds of mucous membrane, called **semilunar folds** (*plicae semilunares coli*). In the sigmoid flexure the longitudinal fibres become more scattered; but upon its lower part, and around the rectum, they spread out and form a layer which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where two accentuations exist, than on the lateral surfaces. In the rectum the external fibres of the longitudinal layer descend and are inserted into the fascia covering the *levator ani* muscle. The middle fibres are mingled with descending fibres of the *levator ani* and terminate by attachment to the rectal wall. The internal fibres descend between the External and Internal sphincter muscles and are inserted into the superficial fascia around the anal margin. The lower part of the rectum is surrounded by the *levator ani* muscle (p. 451). In addition to the muscular fibres of the bowels, two bands of plain muscular tissue are to be noted. They arise from the front of the second and third coccygeal vertebrae, and pass downward and forward to blend with the longitudinal muscular fibres on the posterior wall of the rectum. Each is known as the **rectococcygeal muscle** (*m. rectococcygeus*).

The **Circular Fibres** form a thin layer over the caecum and colon, being especially accumulated in the intervals between the sacculi. In the rectum the circular fibres constitute a thick coat at some portions of the circumference and a thinner coat at others. The circular fibres are thickened at every flexure. The thickenings only partly surround the gut, and hence are not to be considered as additional sphincters. Tuttle calls them the **semicircular muscles of the rectum**. These semicircular muscles are opposite the insertion of Houston’s valves. At the lower end of the rectum the circular fibres become very numerous and constitute the **Internal sphincter muscle** (*m. sphincter ani internus*) (Fig. 930). Tuttle describes it as follows: “This muscle, composed of an aggregation of circular fibres, begins about 4 cm. above the anal margin, and gradually increases in thickness until it reaches the ano-rectal line, after which it thins out again and disappears about the middle
of the anal canal. Its width from above downward averages 1 to 3 cm. (three-fifths of an inch to one and one-fifth inches). Its thickness is so variable that no accurate measurement can be given. Its lower fibres are below and within the grasp of the External sphincter, from which it is separated by a narrow zone of connective tissue. A depressed zone, not always perceptible to the eye, but appreciable by digital touch, marks the line of division between these two muscles. The Internal sphincter is an involuntary muscle. The external sphincter muscle is not a portion of the wall of the bowel. It is described on pages 450 and 451.

The Areolar Coat or Submucous Coat (tela submucosa).—The areolar or submucous coat connects the muscular and mucous layers closely together. This coat is thicker, looser, and more elastic in the rectum than elsewhere. In this coat are the blood-vessels, nerves, and lymphatics.

The Mucous Membrane (tunica mucosa).—The mucous membrane, in the caecum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the oesophagus.

The rectum contains certain horizontal folds. Most of them disappear when the gut is distended, but some of them do not disappear, but remain as distinct folds with free crescentic edges. These permanent folds were first described by Houston, of Dublin, and are known as rectal valves or Houston's valves (plicae transversales recti) (Figs. 928 and 929). Each fold surrounds more than one-third of the gut, and is composed of mucous membrane, submucous tissue, and a layer from the circular muscular layer of the gut. There may be three, four, or five of these folds. Three of them are constant. One is on the right rectal wall, about the point of peritoneal reflection; another is on the left side, about one inch above the margin of the anal canal. A third is on the rectal wall, either toward the right or left, at the point where the rectum joins the front of the sigmoid. These shelf-like valves are not perfectly flat, for on the superior surface of each is a depression.

The borders of a valve are thinner than its base and are very flexible. These valves support the mass of faeces as itdescends, and give to it a rotary motion

THE RECTUM

(Tuttle). In the lower end of the rectum the mucous membrane forms longitudinal folds known as the columns of Morgagni or the rectal columns (columnae rectales [Morgagni]) (Figs. 930 and 931). There are from five to ten of these folds, each of which is about one-half an inch long, and they contain longitudinal muscle-fibres. They are most prominent when the sphincter contracts. The base of each column helps to form the upper margin of the anal canal. The outer angle of each column below passes into a semilunar valve. The grooves between the columns are shallow above and deeper below, and end in the semilunar valves. The semilunar valves, valves of Morgagni or anal valves (Figs. 930 and 921) are folds which stretch from the base of one column to another, and form the anal pockets or crypts of Morgagni (sinus rectales). These pockets are about 5 mm. in depth. They are most marked posteriorly (Ball), but none exists in either the anterior or posterior commissure (Tuttle). Below the sinuses is the white line of Hilton (annulus haemorrhoidalis) (Fig. 931), which reaches to the region where hair and sebaceous glands appear.

As in the small intestine, the mucous membrane consists of a muscular layer, the muscularis mucosae (Fig. 935); of a quantity of retiform tissue in which the vessels ramify; of a basement-membrane and epithelium, which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. In the rectum the epithelial cells are columnar; at the lower end of the tube, however, they begin to change into stratified polyhedrons and prisms. The mucous membrane of the large intestine presents for examination simple follicles and solitary glands.

The Simple Follicles, Intestinal Glands, Crypts or Glands of Lieberkühn (glandulae intestinales [Lieberkuhni]) (Fig. 935) are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and are placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.
The Solitary Glands (noduli lymphatici solitarii) (Fig. 935) in the large intestine are most abundant in the caecum and vermiform appendix, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels of the Large Intestine.—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The caecum, the appendix, and the ileo-caecal valve are supplied by the branches from the anastomotic loops between the right colic and ileo-

colic branches of the superior mesenteric artery (Figs. 932 and 933). In males the sole blood-supply of the appendix is by the appendicular artery from the posterior ileo-caecal branch of the ileo-caecal artery (Fig. 933). In the female the appendix occasionally receives an additional vessel along the appendiculo-ovarian ligament from the ovarian artery. The ascending colon is supplied by the right colic, and the transverse colon by the middle colic branch of the superior mesenteric. The descending colon is supplied by the left colic branch of the inferior mesenteric, and the sigmoid flexure by the sigmoid branches of the inferior mesenteric. The rectum (Fig. 934) is supplied mainly by the superior haemorrhoidal branch of the inferior mesenteric, but also at its lower end by the middle haemorrhoidal from the internal iliac, and the inferior haemorrhoidal from the pudic artery. The super-
rior haemorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other, as far as the internal sphincter, where they anastomose with the other haemorrhoidal arteries and form a series of loops around the anus. The veins of the large intestine correspond to the arteries and join the superior and inferior mesenteric veins which join the portal vein. The veins of the rectum (Fig. 934) commence in a plexus of vessels which surrounds the lower extremity of the intestinal canal. In the vessels forming this plexus are small saccular dilatations just within the margin of the anus (Figs. 931 and 934); from it about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about five inches, running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior haemorrhoidal vein, which empties into the inferior mesenteric branch of the portal vein. This arrangement is termed the haemorrhoidal plexus (Fig. 473); it communicates with the tributaries of the middle and inferior haemorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The inferior haemorrhoidal veins empty into the internal pudic veins, and the middle haemorrhoidal veins empty into the internal iliac veins.

The Lymphatics of the Large Intestine.—The lymphatics of the large intestine begin in the mucous membrane and form an extensive plexus in the submucosa. There are also lymphatics more deeply seated, beneath the simple follicles. Those from the ascending colon and transverse colon open into the glands within the mesocolon and behind the colon (mesocolic glands), from which glands trunks pass to the superior mesenteric glands. The lymphatics from the transverse colon join with lymph-vessels of the great omentum, and hence communicate with the lymphatics of the greater curvature of the stomach. The lymph from the descending colon, from the sigmoid and from the pelvic colon passes to
the glands along the inferior mesenteric artery. The lymphatics of the rectum pass first to the rectal glands, which lie on the muscular coat of the rectum, next to the glands which lie back of the rectum along the superior haemorrhoidal artery, and finally to the sacral glands. Lymphatics from the skin of the anus pass with the lymphatics of the skin to the superficial inguinal glands. Lymphatics from the anus between the skin margin and Hilton’s white line pass to the hypogastric glands.

The Nerves of the Anus and Rectum.—The nerves of the anus and rectum are derived from both the sympathetic and cerebro-spinal system. The chief supply of the rectum is from the mesenteric, sacral, and hypogastric plexuses of the sympathetic. It also obtains small branches from the third, fourth, and fifth sacral nerves. The lower part of the rectum is much more sensitive than the upper part. The muscles of the anus and rectum are supplied “from the intricate plexuses formed by the second, third, fourth, and fifth sacral nerves” (Tuttle). The External sphincter is supplied by nerves which contain motor, sensory, and sympathetic fibres. These nerves come from three sources. “Two filaments from the branches formed by the third, fourth, and fifth sacral nerves extend transversely across the ischio-rectal fossa and distribute themselves to the middle portion of the muscle and to the peri-anal cutaneous surface; a filament which comes off from the internal pudic just before its division into terminal branches supplies the anterior portion of the muscle, and is called the anterior sphincterian nerve; while a filament coming off from the fifth and sixth sacral nerves passes down into the hollow of the sacrum, between the Levator ani muscle and the rectococcygeus ligament, and finally reaches the posterior superficial surface of the External sphincter.”¹ The spinal centre for the nerves of the anus and rectum is opposite the first lumbar vertebra, and is in practically the same region as the centre for the genito-urinary organs.

Movements and Innervation of the Intestines.

Movements.—As the small intestine is devoid of any sphincter arrangement peristalsis cannot mix the food as it does in the pyloric portion of the stomach. The process by which the food is mixed with the secretions and is brought against the intestinal wall for absorption is called by Cannon “rhythmic segmentation.” Rhythmic motions, according to Cannon, “mix the

¹ Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle
food and expose it to the mucosa without advancing it *appreciably* along the canal."1 In this process constrictions occur in the circular fibres, with the result that a collection of stationary food is divided into a number of segments. In the middle of each segment constrictions appear and the earlier constrictions relax. Then the later constrictions relax and the earlier reappear and so on until the food is thoroughly mixed with digestive secretions. Finally the food is driven on by peristalsis coming again to rest and being again subjected to "rhythmic segmentation."2 Cannon says that in the duodenum "rhythmic segmentation" lasts for several minutes, but in other parts of the intestine it may continue for half an hour or more, the food which is being subjected to it scarcely moving along the canal. Cannon infers that in man there are from seven to eight segmentations per minute in a given area. It is probable that there is a sphincter action at the ileo-caecal opening.

Cannon divides the large intestine into two parts: a distal part, in which the material is hard and lumpy and is "advanced by rings of tonic contraction," and a proximal part, in which the material is soft. In this part "the common movements are waves of constriction running backward toward the caecum."3 The resistance of the valve or sphincter enables reversed peristalsis or antiperistalsis to mix the food. When more food enters from the small intestine, antiperistalsis ceases, tonic contraction of the caecum and proximal portion of the colon occurs, some of the food is merged into the transverse colon, and antiperistalsis again begins to act on what remains.4 The above facts have been observed in animals and are probably true in man.

**Innervation.**—The pneumogastric fibres of the small intestine seem to excite contraction of the circular fibres after a brief preliminary period of inhibition.5 Some observers maintain that the splanchnic fibres are inhibitory, but others claim that they are also motor. The local reflex of the small intestine is in Auerbach’s plexus. Cannon quotes Bayliss and Starling to the effect that the pelvic visceral nerves to the large intestine, "arising like the vagus from the central nervous system, are augmentary nerves, whereas the supply from the sympathetic system is purely inhibitory in its action."6 It is further contended that the pelvic visceral nerves are distributed to the distal colon only. "The region of antiperistalsis does not, therefore, receive motor impulses from the pelvic nerves."7

**Surface Form.**—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—i.e., the left lumbar and inguinal regions and the left half of the umbilical region—while the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also in the hypogastric region. The caecum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal region, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct bulge. The position of the base of the veriform appendix is indicated by a point two inches from the anterior superior spinous process of the ilium, on a line drawn from this process to the umbilicus. This is known as McBurney’s point. Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior spines of the ilia and marking the point where this line intersects the right semilunar line.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculæ seminales can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston’s folds. The ischio-rectal fossæ can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel. By gradual dilatation of the sphincter, the whole hand can be

introduced into the rectum so as to reach the descending colon. This method of exploration is not at the present day employed for diagnostic purposes.

**Surgical Anatomy.**—The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one fold glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and lacerated. *Wounds* of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, there may be no extravasation of the contents of the bowel. The mucous membrane becomes everted and perhaps plugs the little opening. The bowels, therefore, may be punctured with a fine capillary trocar, in cases of excessive distention of the intestine with gas, without much danger of extravasation. A longitudinal wound gaps more than a transverse wound, owing to the greater thickness of the circular muscular coat. In closing a wound of the intestine, use Lembert’s inversion sutures, which bring the peritoneal surfaces in contact. Halsted showed us that these sutures must include the tough submucous coat. The portions of intestine which lie in the pelvis are inflamed in *pelvic peritonitis* and become embedded in adhesions. The portions of intestine which may be present are the termination of the ileum, the portion of small intestine with the largest mesentery (Treves), the rectum, and the pelvic colon. The small intestine, and most frequently the ileum, may become *strangulated* by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or adherent omentum from the same cause; or the band may be formed by Meckel’s diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicae, or an adherent vermiform appendix or Fallopian tube. *Intussusception* or invagination of the small intestine may take place in any part of the jejenum and ileum, but the most frequent situation is at the ileo-caecal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. *Stricture, the impaction of foreign bodies,* and twisting of the gut (vomitus) may lead to intestinal obstruction. Volvulus is most common in the sigmoid flexure. Meckel’s diverticulum may itself become twisted and strangulated.

**Resection** of a portion of the intestine may be required in cases of gangrenous gut; in cases of intussusception; for the removal of new growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy,* and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the gut must be clamped on either side of this portion in order to prevent the escape of any of the contents of the bowel during the operation. The portion of bowel is then separated above and below by means of scissors. If the portion removed is small, it may be simply removed from the mesentery at its attachment and the bleeding vessels tied; but if it is large, it will be necessary to remove also a triangular piece of the mesentery, and having secured the vessels, suture the cut edges of this structure together. The surgeon then proceeds to unite the cut ends of the bowel together. He may do it by the operation termed *end-to-end anastomosis.* There are many ways of doing this, which may be divided into two classes: one, where the anastomosis is made by means of some mechanical appliance, such as Murphy’s button, or one of the forms of decalciﬁed bone bobbins; and the other, where the operation is performed by simply suturing the ends of the bowel in such a manner that the peritoneum covering the free divided ends of the bowel is brought into contact, so that speedy union may ensue.

In some cases after resection each open end of the gut is closed, the side of the terminal portion is sutured to the side of the initial portion, a fistula is made in each, and the suturing is completed so as to cause the two fistulae to correspond. A permanent side-to-side opening is thus made. *Lateral anastomosis* without resection may be practised between two pieces of intestine, in order to side-track an intervening portion, which is the seat of malignant disease or of an artiﬁcial anus. *Complete exclusion* of a portion of intestine is performed for irremovable tumors or persistent fecal fistulae of the large intestine. The intestine is cut through above and below the diseased area and the ends of the healthy gut are united to each other, or the larger end is closed, an opening is made into the side of the larger end and the smaller end is implanted in it (lateral implantation). The two ends of the excluded portion are fastened to the skin and are left open.

In ascites resulting from cirrhosis of the liver benefit occasionally follows the performance of Talma’s operation (epiploecy). The abdomen is opened and the omentum is sutured to the anterior abdominal wall or in the abdominal wound in the hope of establishing a more free communication between the portal and systemic circulations, thus lowering portal pressure.

External hernia is considered on page 1325.

By the term *internal hernia,* we mean hernia into the foramen of Winslow, into the retro-
The duodenal fossa, into the retro-caecal fossa, or into the intersigmoid fossa. Such a hernia produces the symptoms of acute strangulation of the intestine.

In typhoid fever there is ulceration of Peyer's patches. One of these ulcers may perforate. The only chance for life is immediate laparotomy and closure of the perforation. This saves one-fifth, or possibly one-third, of the cases. The incision is made to expose the lower ileum, as in the vast majority of cases the perforation is in this portion of the gut.

Ulcer of the duodenum is more common than used to be thought. The portion of the duodenum between the pylorus and the bile papilla is about four inches in length, and is called by the Mayo brothers the vestibule of the duodenum. Here the acid gastric juice enters and may produce an ulcer. The portion of the duodenum below the vestibule is not liable to ulcer, because it is protected by the alkaline bile and pancreatic juice.

A duodenal ulcer may perforate a large duodenal vessel and cause death from hemorrhage, or may perforate the intestine and produce septic peritonitis. A perforated ulcer is treated by laparotomy and closure of the perforation. Occasionally ulceration of the duodenal glands (Curling's ulcer) may occur in cases of burns, but is not a very common complication.

The vermiform appendix is very liable to become inflamed, the condition being known as appendicitis. This condition may be set up by a catarrh of inflammation arising in the appendix or derived from the colon. It may remain catarhal and then subside. It may become purulent or may be purulent from the beginning. Anything which lessens vital resistance makes the appendix a ready prey to bacteria. Among causes which lessen resistance are febrile concretions, twists of the mesoappendix cutting off the blood-supply, bruises inflicted by the Psoas muscle (Byron Robinson), blocking of the outlet of the appendix by catarrhul exudate, concretions, proliferted lymphoid tissue, or adhesions. Appendicitis may arise by the appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distention of the caecum. As the result of inflammation, its blood-supply, which is mainly through one large artery running in the mesoappendix, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of feces or a foreign body in the appendix. The inflammation may result in ulceration and perforation, or in gangrene of the appendix the appendix may be blocked and full of pus, or abscess may form outside of it (appendicular abscess). These conditions require prompt operative interference, and in cases of recurrent attacks of appendicitis it is advisable to remove this diverticulum between the attacks. In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved, it is usually the caecum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. The diameter of the large intestine gradually diminishes from the caecum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the caecum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distention is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The caecum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to give way from the distention, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesosigmoid is elongated. The gut at this part being loaded with feces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no invagination of the epiblast, and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the invagination of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath and thus favors prolapse, especially in children. The vessels of the rectum are arranged as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about five inches in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this point by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a depen-
dent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing and tends to cause a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. The membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas’s pouch. The recto-vesical pouch of peritoneum extends to within three inches from the anus, so that it is not desirable to remove more than two and a half inches of the entire circumference of the bowel, for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas’s pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is advisable to remove a less length of the tube in this sex. Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with iodoform gauze until the operation is completed and then the edges of the wound in the peritoneum is accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin, and the greater and lesser sacro-sciatic ligaments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downward and inward through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outward, the whole of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portions of the gut, if healthy. The two divided ends of the gut can perhaps then be approximated and sutured together. Kraske’s operation is in many cases preceded by the performance of iliac colostomy. In cancer high up in the rectum removal of the growth through the abdomen is sometimes practised, the divided lower end of the rectum being sutured to the divided upper end (Weir’s operation).

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum, as soon as the disease is recognized, in the hope that the rate of growth may be retarded by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of colostomy may be performed either in the inguinal or lumbar region; but inguinal colostomy (Mayell’s operation) has at the present day superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process can be formed which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being surrounded by peritoneum, a coil can be drawn out of the wound, and when it is opened transversely a spur is formed, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupard’s ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewed to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by pushing a glass bar through a slit in the mesocolon. The two parts of the loop are sutured together. The intestine is now sutured to the parietal peritoneum. The wound is dressed, and either immediately or between the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened. It is opened transversely with the Paquelin cautery.

THE LIVER (HEPAR) (Figs. 936, 937, 938, 939).

The liver is the largest gland in the body, and is situated in the upper and right part of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and extending into the left hypochondrium as far as the mammary line. In the male it weighs from fifty to sixty.
ounces; in the female, from forty to fifty. It is relatively much larger in the fœtus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body-weight. Its greatest transverse measurement is from eight to nine inches. Vertically, near its lateral or right surface, it measures about six or seven inches, while its greatest antero-posterior diameter is on a level with the upper end of the right kidney and is from four to five inches. Opposite the vertebral column its measurement from before backward is reduced to about three inches. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its color is a dark reddish-brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape, it must be hardened in situ, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge toward the left. Symington describes its shape as that “of a right-angled triangular prism with the right angles rounded off.” It possesses five surfaces, viz., a superior, inferior, anterior, posterior, and a right lateral surface.

The superior and anterior surfaces are separated from each other by a thick rounded border, and are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the suspensory or falciform ligament, which divides the liver into two unequal parts, termed the right and left lobes (Figs. 936, 940, and 941). Except along the line of attachment of this ligament to the liver, the superior and anterior surfaces are covered by peritoneum.

The Superior Area or Surface (facies superior) (Fig. 936).—The superior area or surface comprises a part of both lobes. Spalteholz considers as parts of the superior surface the right surface and the anterior surface. The superior surface is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, the cardiac depression (impressio cardiaca), which corresponds with the position of the heart on the upper surface of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is continued into the under surface by a prominent sharp margin.

The Anterior Area or Surface.—The anterior area or surface is large and triangular in shape, comprising also a part of both lobes. It is directed forward,
and the greater part of it is in contact with the Diaphragm, which separates it from the right lower ribs and their cartilages. In the middle line it lies behind the ensiform cartilage, to the left of which it is protected by the seventh and eighth left costal cartilages. In the angle between the diverging rib cartilages of opposite sides the anterior surface is in contact with the abdominal wall. It
is continuous with the inferior surface by a sharp margin, and with the superior and lateral surfaces by thick rounded borders.

**The Lateral or Right Area or Surface** (Figs. 936 and 938).—The lateral or right area or surface is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the left pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

**The Under or Visceral Area or Surface** (jacies inferior) (Figs. 938 and 939).—The under or visceral area or surface is uneven, concave, directed downward and backward and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney. The surface is divided by a longitudinal fissure into a right and a left lobe, and is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the blood-vessels and duct of the viscus. The under surface of the left lobe presents to the right and near the centre a rounded eminence, the omental tuberosity (tuber omentale) (Fig. 938), which is in contact with the lesser omentum. It is surrounded by a broad depression, the gastric surface or impression (impressio gastrica), with which the stomach is in contact. Between the gall-bladder and the left lobe is the quadrate lobe. The quadrato lobe is bounded to the left by the umbilical fissure or the fissure of the umbilical vein (fossa venae umbilicales), which is the anterior portion of the longitudinal fissure and lodges the round ligament (ligamentum teres). The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the gall-bladder and is called the fossa vesicalis (fossa vesicae felleae); the portion to the left, the smaller of the two, is somewhat oblong in shape, its antero-posterior diameter being greater than its transverse. It is known as the quadrato lobe (lobus quadratus), and is in relation with the pyloric end of the stomach (impressio pylorica) and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow concave impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the colic impression (impressio colica), is produced by the hepatic flexure of the colon; the posterior, the renal impression (impressio renalis), is occupied by the upper end of the right kidney (Fig. 938). To the inner side of the latter impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the duodenal impression (impressio duodenalis). Just in front of the vena cava is a narrow strip of liver tissue, the caudate lobe, which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. Immediately below it is the foramen of Winslow.

**The Posterior Area or Surface** (jacies posterior) (Figs. 937 and 939).—The posterior area or surface is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this uncovered area (Fig. 938) is about three inches broad, and is in direct contact with the Diaphragm, being united to it by areolar tissue. In this tissue are numerous small veins which join the portal circulation to the systemic circulation. The uncovered area is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament. It is in the same way marked off from the under surface of the liver by the line of reflection of the lower layer of the coronary ligament (Fig. 940). In its centre the posterior surface is deeply notched for the vertebral column and crura of the Diaphragm, and to the right of this it is indented for the inferior vena cava (fossa venae cavae), which is often
partly embedded in its substance. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area, the **suprarenal impression** (*impressio suprarenalis*) (Fig. 938), the greater part of which is devoid of peritoneum; it lodges the right suprarenal capsule, which is inserted between the liver and Diaphragm. To the left of the fossa for the inferior vena cava is the **Spigelian lobe**, which lies between the **fissure for the vena cava** and the fissure for the **ductus venosus**. Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the **tuberculum papillare** (Fig. 938). It is opposite the tenth and eleventh dorsal vertebrae, and rests upon the aorta and crura of the Diaphragm, being covered by the peritoneum of the lesser sac. The lobe is nearly vertical in position, and is directed backward; it is longer from above downward than from side to side, and is somewhat concave in the transverse direction. On the posterior surface to the left of the Spigelian lobe is a groove, the **oesophageal groove** (*impressio oesophagea*), indicating the position of the abdominal portion of the oesophagus (Fig. 938).

Prof. Cunningham divides the liver into two surfaces, a **visceral** and a **parietal**, and subdivides the parietal surface into a **posterior area** and **superior area**, an **anterior area** and a **right area**. The parietal surface is separated from the visceral surface by the inferior border or margin.

The **inferior border or margin** (*margo inferioris*), posteriorly, is rather ill defined. It is the lower margin of the posterior surface; it follows the line of rib and is in contact with the right kidney. At the right side the lower margin is thick and distinct, and, as a rule, projects slightly below the thorax. The front of the inferior margin is called the **anterior margin** (*margo anterior*). It is a sharp edge which, on inspiration, corresponds to an oblique line on the abdominal wall drawn from "a point half an inch below the margin of the ribs (tip of tenth costal cartilage), on the right side, to a point an inch below the nipple on the left, and extending down in the middle line to a point half-way between the gladiolus and the umbilicus."\(^1\)

In men the anterior margin of the liver often corresponds to the lower margin of the ribs, but in women and children it is usually below the ribs in the line

\(^1\) Ambrose Birmingham, in Cunningham's Text-book of Anatomy.
indicated above. Opposite the attachment of the falciform ligament the anterior border often exhibits a deep notch, the **umbilical notch** (incisura umbilicalis), which is the anterior end of the fossa venae umbilicales. Another notch, sometimes present, corresponds to the fundus of the gall-bladder, and is known as the **notch of the gall-bladder** (incisura vesicae felleae).

The **left extremity of the inferior margin of the liver** is thin and flattened from above downward. The margin passes posteriorly around the free end of the left lobe and terminates posteriorly at the oesophageal groove.

**Fissures.**—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are: the **umbilical fissure**, the **fissure of the ductus venosus**, the **transverse fissure**, the **fissure for the gall-bladder**, and the **fissure for the inferior vena cava**. They are arranged in the form of the letter H. The left limb of the H is known as the **longitudinal fissure**. The right limb is formed in front by the **fissure for the gall-bladder**, and behind by the **fissure for the inferior vena cava**; these two fissures are separated from each other by the caudate lobe. The connecting bar of the H is the **transverse** or **portal fissure**. It separates the quadrate lobe in front from the caudate and Spigelian lobes behind.

![Diagram of the liver](image)

_Fig. 939.—Posterior and under surfaces of the liver._ (From Ellis.)

**The Longitudinal Fossa or Fissure (fossa longitudinalis sinistra).**—The longitudinal fissure is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ. It separates the right and left lobes; the **Transverse Fissure** (Fig. 938) joins it, at right angles, and divides it into two parts. The anterior part is called the **umbilical fossa or fissure** (fossa venae umbilicalis) (Fig. 938); it is deeper than the posterior, and lodges the umbilical vein in the foetus, and its remains (the round ligament) in the adult; the posterior part contains the ductus venosus, and is known as the **fissure of the ductus venosus**. This fissure lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the **pons hepati**.

The **Fissure or Fossa of the Ductus Venosus** (fossa ductus venosi) (Fig. 938) is the back part of the longitudinal fissure, and is situated mainly on the posterior surface of the liver. It lies between the left lobe and the lobe of Spigelius. It
lodges in the foetus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The Transverse or Portal Fissure (porta hepatis) (Fig. 938).—The transverse or portal fissure is a short but deep fissure, about two inches in length, extending transversely across the under surface of the left portion of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. By the older anatomists this fissure was considered the gateway (porta) of the liver; hence the large vein which enters at this fissure was called the portal vein (Fig. 939). Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The Fossa or Fissure for the Gall-bladder (fossa vesicae felleae).—The fossa or fissure for the gall-bladder is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to the right extremity of the transverse fissure.

The Fissure or Fossa for the Inferior Vena Cava (fossa venae cavae) (Fig. 938).—The fissure or fossa for the inferior vena cava is a short, deep fissure, in some cases a complete canal, in consequence of the substance of the liver occasionally surrounding the vena cava. It extends obliquely upward from the lobus caudatus, which separates it from the transverse fissure, on the posterior surface of the liver, and separates the Spigelian from the right lobe. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelii, and the lobus caudatus, the last three being merely parts of the right lobe.

The Right Lobe (lobus hepatis dexter) (Figs. 936 and 938).—The right lobe is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper and anterior surfaces by the falciiform ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava, which separate its left part into three smaller lobes—the lobus Spigelii, lobus quadratus, and lobus caudatus. On it are seen four shallow impressions: one in front, for the hepatic flexure of the colon; a second behind, for the right kidney; a third internal, between the last-named and the gall-bladder, for the second part of the duodenum; and a fourth on its posterior surface, for the suprarenal capsule.

The Lobus Quadratus or Square Lobe (Figs. 938 and 939) is situated on the under surface of the right lobe, is bounded in front by the inferior margin of the liver; behind, by the transverse fissure; on the right, by the fissure of the gall-bladder; on the left, by the umbilical fissure.

The Lobus Spigelii (lobus caudatus [Spigelii]) (Figs. 938 and 939) is situated upon the posterior surface of the right lobe of the liver. It looks directly backward, and is nearly vertical in direction. It is bounded, above, by the upper layer of the coronary ligament; below, by the transverse fissure; on the right, by the fissure for the vena cava; and on the left, by the fissure for the ductus venosus. Its left upper angle forms part of the groove for the oesophagus. What is here called the lobus Spigelii, Spalteholz calls the lobus caudatus of Spigelius.
The Lobe Caudatus or Tuberculum Caudatum (processus caudatus) (Fig. 938), or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward, from the lower extremity of the Spigelian lobe to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava. What is here called the lobus caudatus, Spalteholz calls the processus caudatus of the lobus caudatus of Spigelius.

The Left Lobe (lobus hepatis sinister) (Figs. 936 and 938).—The left lobe is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex; its under surface is concave, and presents a shallow depression for the stomach, the gastric impression. This is situated in front of the groove for the oesophagus, and is separated from the longitudinal fissure by the omental tuberosity, which lies against the small omentum and lesser curvature of the stomach. The posterior end of the left lobe frequently exhibits a flat projection, composed of connective tissue, and called the appendix fibrosa hepatis. In the adult, portions only of bile-ducts are present in it. In the newborn it is a definite portion of secreting liver substance, which later undergoes connective-tissue transformation.

Ligaments.—The liver is connected to the under surface of the Diaphragm and the anterior walls of the abdomen and the inferior vena cava by six ligaments, four of which are peritoneal folds; the other two, which are the round ligament and the ligament of the ductus venosus, are fibrous cords, resulting from the obliteration of foetal vessels. These ligaments are the falciform, two lateral, coronary, round, and the ligament of the ductus venosus. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum.

The Falciform, Broad or Suspensory Ligament (ligamentum falciforme hepatis) (Figs. 936, 940, and 941).—The falciform or suspensory ligament is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the sheath of the right Rectus muscle to within one inch of the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface.

The free edge or base of the falciform ligament reaches from a little above and to the right of the umbilicus to the umbilical fissure on the anterior margin of the liver. This free edge contains between its folds the round ligament of the liver. On the posterior surface of the liver the two peritoneal folds which constitute the falciform ligament separate, the right fold passing into the upper fold of the coronary ligament, the left fold passing into the upper fold of the left lateral ligament.
The Lateral Ligaments (Figs. 936 and 940).—The lateral ligaments are two in number, and are called the right and left lateral ligaments.

The Right Lateral Ligament (ligamentum triangulare dextrum) (Figs. 936 and 940) is in reality the right extremity of the coronary ligament. This ligament is triangular in form, runs from the liver to the Diaphragm, and is formed by the apposition of the upper and lower layers of the coronary ligament. It is attached to the liver between its lateral and inferior surfaces.

The Left Lateral Ligament (ligamentum triangulare sinistrum) (Figs. 936 and 940) is also formed by apposition of the upper and lower layers of the coronary ligament. It is triangular in form, runs from the liver to the Diaphragm, and is longer than the right lateral ligament. It is attached to the upper surface of the left lobe, where it lies, in front of the oesophageal opening in the Diaphragm.

The Coronary Ligament (ligamentum coronarium hepatis) (Figs. 936 and 940).—The coronary ligament connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm on to the upper and lower margins of the posterior surface of the liver. The coronary ligament consists of two layers, which are continuous on each side with the lateral ligaments, and, in front, with the falciform ligament. Between the layers a large triangular area is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.

The Round Ligament (ligamentum teres hepatis) (Figs. 939 and 941).—The round ligament is a fibrous cord resulting from the obliteration of the fœtal umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the umbilical fissure on the under surface of the liver, to the left branch of the portal vein.

The Ligament of the Ductus Venosus (ligamentum venosum [Arantii]) is composed of slender bundles of fibrous tissue, and results from the obliteration of the ductus venosus of the fœtus. It arises from the left branch of the portal vein, almost opposite the insertion of the round ligament, passes backward in the fissure of the ductus venosus, and, as it emerges from the liver, is attached to the vena cava.

Support and Movability of the Liver.—The liver is movable within certain narrow limits. It moves with respiration. On inspiration it moves down with the Diaphragm to distinctly below the costal arch in the right nipple line. Much discussion has taken place as to what supports the liver in place. Symington asserted that the ligaments do not give support, because they lie relaxed. Other observers (Graham, Steele) apparently demonstrate that the peritoneal ligaments do give some support to the liver. The connective tissue which unites the uncovered area of the right lobe of the liver to the Diaphragm and the hepatic veins which join the vena cava (Faure) do give distinct support. The chief factor in the support of the liver is the intra-abdominal pressure resulting from the tonic contraction of the abdominal muscles. When abdominal tension is normal the intestines are driven up and become a bed for the liver. Intrahepatic vascular tension aids in supporting the liver (Glénard).
Abnormalities of the Liver.—The liver may be divided into many lobules, and such lobulation is most evident on the parietal surface of the right lobe. Lobulation is probably a pathological change. Occasionally the right lobe is small and the left large.

The editor, in performing an abdominal operation, encountered a liver the left lobe of which was so large and the right so small as to suggest transposition or rotation of the organ. Such a change may result from abnormality of the foetal circulation or from syphilitic disease of the right lobe, producing cicatricial contraction. The left lobe may be very small; sometimes it is rudimentary. When the left lobe is very small an unusual amount of stomach is visible, and the entire gall-bladder can be seen from the front. In such a case the gall-bladder is usually displaced and it may actually "lie with its long axis in the transverse axis of the body."

Fig. 942.—Deformed female liver. (Poirier and Charpy.)

Atrophy of the left lobe is usually a congenital defect, but may result from syphilis. Small accessory lobes, about one inch in length, are not uncommon, and they are most often met with on the visceral surface of the right lobe. "When markedly pedunculated, they may form accessory livers. The Spigelian lobe is sometimes curiously pedunculated."

Accessory livers are fragments of hepatic tissue or rests, which are entirely separated from the liver. They are seldom met with. When they do exist their most common situation is in the suspensory ligament, but they have been found in the great omentum, in the peritoneum, wall of the gall-bladder, and in other situations. They may be congenital or may be due to atrophy of the pedicle of an accessory lobe or of a pedunculated lobe. Tight lacing alters the shape and position of the liver (Fig. 942). It may flatten the dome and increase the length of the anterior surface, this change being especially obvious in the right lobe, and a costal groove may be formed by the pressure of a rib. "When the elongated right lobe passes over the right kidney, there is atrophy of the hepatic substance"

1 H. D. Rolleston on Diseases of the Liver.  2 Ibid.  3 Ibid.
and thickening of the capsule, which is opaque and forms a hinge-like ligament between the main part of the right lobe above and the constricted lower portion. This lobe is variously termed partial hepatoptosis, constriction lobe, or the sustentacular formation of the right lobe (Hertz). The constriction furrow is produced by the pressure of the corset in front and the resistance of the kidney behind. The constriction lobe tapers to a point, so that the shape of the liver, as seen from the front, is that of a right-angled triangle, with the apex downward.¹ The condition resembles Riedel's lobe. The left lobe may also project down, but not so markedly. Tight lacing may cause the entire organ to occupy a level higher than normal. Such a liver is thick and excessively convex above and thin below, and reaches to or laps over the spleen. In severe cases the superior surface is thrown into antero-posterior creases or folds. Linguiform or tongue-like lobe, Riedel's lobe or floating lobe (Fig. 942), may be congenital, may be due to tight lacing, or may arise in cholelithiasis or cholecystitis from the traction of adhesions. Such a lobe comes off from the right lobe. It may be a tapering mass of liver tissue, it may have a thin pedicle of liver tissue, or its pedicle may be merely a double fold of peritoneum. The gall-bladder may lie upon its under surface, or may be placed to the left of it.

Vessels.—The blood-vessels connected with the liver are the hepatic artery, the portal vein and the hepatic veins.

The Hepatic Artery and Portal Vein (Figs. 418, 419, 489, and 944), accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum, and in front of the foramen of Winslow. The hepatic duct, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures in the lesser omentum (Fig. 859) is as follows: the hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They enter the transverse fissure in the above-described order, but in that fissure undergo rearrangement, the duct being in front, the artery in the middle, and the vein behind. The artery, the vein, and the duct divide into a right and left branch and several smaller branches, and within the organ the vessels from the three sources accompany each other and divide at the same points; so each branch of the portal vein is accompanied by a branch of the hepatic artery and of the duct. They are enveloped in a loose areolar tissue, the capsule of Glisson (Fig. 943), which accompanies the vessels in their course through the portal canals in the interior of the organ.

The Hepatic Veins (Fig. 421).—The hepatic veins convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three

¹ Rolleston, on Diseases of the Liver.
veins, which converge toward the posterior surface of the liver and open into the portion of the inferior vena cava situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the vena cava; that from the middle of the organ and lobus Spigelii having a straight course.

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, these veins remain widely open and solitary (Fig. 946), which are more or less collapsed, and always accompanied by an artery and duct. The hepatic veins are destitute of valves.

Structure.—The substance of the liver is composed of lobules held together by extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

The Serous Coat (tunica serosa).—The serous coat is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The Areolar or Fibrous Coat (capsula fibrosa [Glissoni]).—The areolar or fibrous coat lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is thick and evident, is known as the capsule of Glisson, and envelops the vessels which enter the liver and passes with them along the portal canals. The areolar tissue which surrounds and binds together the liver lobules is continuous with the areolar coat.

The Lobules (lobuli hepatis) (Fig. 949).—The lobules form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland. They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower
animals (for example, the pig) they are well defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered around the smallest radicles of the hepatic veins (sublobular veins), to which each is connected by means of a small branch which issues from the centre of the lobule (intralobular vein). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which are ducts and a plexus of vessels, the interlobular plexus (Figs. 948 and 949). In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 946).

Microscopic Appearance.—Each lobule is composed of a mass of cells, hepatic cells (Fig. 945), surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single straight central vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) cells, by which the secretion is formed; (2) blood-vessels, in close relation with the cells, containing the blood from which the secretion is derived; and (3) ducts, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

1. The Hepatic Cells are epithelial in nature and of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the \( \frac{1}{100} \) to the \( \frac{2}{100} \) of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules. As stated above, they are the chief agents in the secretion of the bile.

2. The Blood-vessels.—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The Hepatic Artery, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off vaginal branches which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts,
and the investing membranes of the liver. It also gives off capsular branches which reach the surface of the organ, terminating in the fibrous coat in stellate plexuses. Finally it gives off interlobular branches (rami arteriosi interlobulares) which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this plexus lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The Portal Vein also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson’s capsule, dividing into branches in its course, which finally break up into a plexus, the interlobular plexus, in the interlobular spaces. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 947). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of
the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, forming a number of converging vessels which are connected by transverse branches (Figs. 948 and 949). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells: and here it is that the blood is brought into intimate connection with the liver-cells and the bile is secreted. Arrived at the centre of a lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobule from apex to base and is called the *intralobular* or *central vein* (*vena interlobularis*) (Fig. 949).
base of the lobule this vein opens directly into the sublobular vein, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intra-lobular veins. Finally, the hepatic veins, as mentioned on page 767, converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) The Ducts.—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away. Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed intercellular biliary passages, bile-capillaries or bile-canaliculi (ductus biliferi). These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the angle where three or more liver-cells meet (Fig. 951), and it seems doubtful whether there is any delicate membrane forming the wall of the channel. Heidenhain, however, thinks they have coats. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (interlobular) between the lobules. From this plexus interlobular ducts (ductus interlobulares) are derived which pass into the portal canals, become enclosed in Glisson’s capsule, and, accompanying the portal vein and hepatic artery (Fig. 952), join with other ducts to form two main trunks, the right and left branches of the hepatic duct, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Structure.—The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective-tissue coat, in which are muscle-cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells. In the larger ducts, which lie in the portal canals, there are a number of orifices disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Lymphatics of the Liver (Fig. 506).—The lymphatics in the substance of the liver commence in lymphatic spaces around the capillaries of the lobules; they accompany
the vessels of the interlobular plexus, often enclosing and surrounding them. These unite and form larger vessels, which run in the portal canals, enclosed in Glisson’s capsule, and emerge at the portal fissure to be distributed in the manner described. Other superficial lymphatics arise from the superficial lobules, pass under the peritoneum, and form a close plexus, where this membrane covers the liver. The first-named group of lymphatics give origin to the deep collecting trunks, the second to the superficial collecting trunks. According to Poirier, Cunéo and Delamare,¹ one group of deep collecting trunks accompanies the portal vein, there being fifteen to eighteen of them emerging from the transverse fissure. They empty into the glands of the hilum. Another group accompanies the hepatic veins. There are five or six trunks which pass through the Diaphragm and terminate in the glands about the vena cava (intrathoracic glands). According to the above-cited authorities, the superficial trunks of the superior surface are divided into posterior, anterior, and superior trunks. Some of the posterior trunks terminate in the glands about the coeliac axis, others in the glands about the lower portion of the vena cava in the thorax; others in the glands about the abdominal portion of the oesophagus. The anterior trunks which are limited to the right lobe pass to the glands of the hilum. The superior trunks ascend in the suspensory ligament. Some pass to the glands about the vena cava, just above the Diaphragm; others to the hepatic glands. The balance unite to form a very large trunk, which passes through the Diaphragm and divides into branches which enter the glands back of the junction of the ensiform cartilage.

Nerves of the Liver.—The nerves of the liver are derived from the left pneumogastric and the solar plexus of the sympathetic. The branches of the pneumogastric ascend from in front of the stomach within the lesser omentum. The sympathetic nerves pass along the hepatic artery from the coeliac plexus. The nerves enter the liver at the transverse fissure and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated fibres enter the lobules and ramify between the cells.

The Excretory Apparatus of the Liver.

The excretory apparatus of the liver consists of (1) the hepatic duct, which, as we have seen, is formed by the junction of the two main ducts, which pass out of the liver at the transverse fissure, and are formed by the union of the bile-capillaries; (2) the gall-bladder, which serves as a reservoir for the bile; (3) the cystic duct, which is the duct of the gall-bladder; and (4) the common bile-duct, formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct (ductus hepaticus) (Figs. 953, 954, and 956).—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half or two inches, between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver, between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein (Fig. 944).

The Gall-bladder (vesica fellea) (Figs. 859, 861, 938, 944, and 953).—The gall-bladder is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and fixed in it by connective tissue, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is

¹ The Lymphatics. Translated and edited by Cecil H. Leaf.
about four inches in length, one inch in breadth at its widest part, and holds from
eight to ten drachms. It is divided into a fundus, body, and neck. The fundus
(fundus vesicae felleae), or broad extremity, is
directed downward, forward, and to the right,
and projects beyond the anterior border of the
liver; the body (corpus vesicae felleae) and neck
(collum vesicae felleae) are directed upward and
backward to the left. The neck of the gall-
bladder is on a slightly higher level than the
lowest point of the gall-bladder; thus the weight
of the bile is away from rather than toward
the outlet. The upper surface of the gall-
bladder is attached to the liver by connective
tissue and vessels. The under surface is
covered by peritoneum, which is reflected on to
it from the surface of the liver. Occasionally
the whole of the organ is invested by the ser-
ous membrane, and is then connected to the
liver by a kind of mesentery.

**Relations.**—The body of the gall-bladder is
in relation, by its upper surface, with the
liver, to which it is connected by areolar tissue
and vessels; by its under surface, with the
commencement of the transverse colon; and
farther back, with the upper end of the de-
sceding portion of the duodenum or some-
times with the pyloric end of the stomach or
the first portion of the duodenum. The fundus
is completely invested by peritoneum; it is in
relation, in front, with the abdominal parietes,
immmediately below the ninth costal cartilage;
behind, with the transverse arch of the colon.
The neck is narrow, and curves upon itself like the letter S; at its point of
connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or filled with calculi, the fundus may be felt
through the abdominal parietes, especially in an emaciated subject; the relations of this sac will
also serve to explain the occasional occurrence of abdominal biliary fistulae, through which biliary
calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, du-
donum, or colon, which occasionally happens.

**Structure.**—The gall-bladder consists of three coats—serous, fibrous and mus-
cular, and mucous.

The External or Serous Coat (tunica serosa vesicae felleae) is derived from the perit-
oneum; it completely invests the fundus, but covers the body and neck only on
their under surfaces.

The Fibro-muscular Coat (tunica muscularis vesicae felleae) is a thin but strong
layer which forms the framework of the sac, consisting of dense fibrous tissue which
interlaces in all directions and is mixed with plain muscular fibres which are dis-
posed chiefly in a longitudinal direction, a few running transversely.

The Internal or Mucous Coat (tunica mucosa vesicae felleae) is loosely connected
with the fibrous layer. It is generally tinged with a yellowish-brown color, and
is everywhere elevated into minute rugae, by the union of which numerous meshes
are formed, the depressed intervening spaces having a polygonal outline. The
meshes are smaller at the fundus and neck, being most developed about the centre.
of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of screw-like or spiral valve (Fig. 953).

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the duodenum.

**The Cystic Duct (ductus cysticus).**—The cystic duct, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downward and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. It lies in the gastro-hepatic omentum in front of the portal vein, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve (*valvula spiralis [Heisteri]*) (Fig. 953). When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a sauculated appearance.

**The Ductus Communis Choledochus or Common Bile-duct (ductus choledochus)** (Figs. 953 and 954), the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, is of the diameter of a goose-quill, and is formed by the junction of the cystic and hepatic ducts.

It descends within the two layers and along the right border of the lesser omentum behind the first portion the duodenum, in front of the portal vein, and to the right of the hepatic artery (Fig. 859); then passes either between the pancreas and descending portion of the duodenum, or through the head of the pancreas. In fifty-eight dissections Prof. Büngner found that it passed through the pancreas fifty-five times and over the head only three times. Even when it passes through the pancreas it almost always joins the pancreatic duct outside of the gland. It descends by the right side of the pancreatic duct and passes with it obliquely through the wall of the descending portion of the duodenum between the mucous and muscular coats in the submucous tissue for one-half to three-
quarters of an inch. The two ducts usually unite just before opening into the duodenum (Figs. 954, 955, and 957), but may remain independent throughout. The ampulla of Vater (Fig. 954) is the cavity formed by the fusion of the two ducts, and is much larger than the opening on the bile-papilla. The two ducts open by a common orifice, or by two separate orifices, upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches below the pylorus. The muscle of the common duct has a certain amount of sphincter power (Fig. 955), which serves to prevent the entrance of duodenal contents through the small aperture, but is not sufficiently powerful to prevent the flow of bile and pancreatic juice.

Structure.—The coats of the large biliary ducts are an external or fibrous and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissues, with a certain amount of muscular tissue arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts. It is questionable if the smallest biliary ducts, which lie in the interlobular spaces, have any coats. Heidenhain thinks they have a connective-tissue coat, in which are muscle-cells arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells.

Dimensions of the Bile-ducts.—The hepatic duct is about two inches in length, and its lumen is one-sixth of an inch in diameter. The cystic duct is about one and one-half inches in length, and its lumen one-twelfth of an inch in diameter. The common duct is about three inches in length, and its lumen is one-quarter of an inch in diameter. The duodenal opening is smaller than the common duct. The ducts are capable of considerable distention, but the duodenal opening cannot be dilated (Hyrtl).
Blood-vessels, Lymphatics and Nerves of the Gall-bladder and Bile-ducts.—The cystic artery (Fig. 418), a branch from the right division of the hepatic, supplies the gall-bladder and cystic duct with blood. It passes along the cystic duct, and on reaching the gall-bladder divides into an upper branch and a lower branch. The upper branch lies between the gall-bladder and the liver and sends branches to each. The lower branch is between the peritoneum and the wall of the gall-bladder. The cystic veins empty into the portal vein. The common duct receives branches from the superior pancreatico-duodenal artery. There is a submucous lymphatic network and a muscular lymphatic network. The lymphatics are much less numerous at the fundus of the gall-bladder than at the neck or in the extra-hepatic ducts. The collecting trunks (Fig. 506) end in glands along the cystic and common ducts, and these glands are in communication with the duodenal lymphatics and the lymphatics from the head of the pancreas. The nerves of the gall-bladder and bile-ducts come from the coeliac plexus of the sympathetic. The adjacent peritoneum is plentifully supplied with nerves (Byron Robinson).

The Bile (jel).—The bile is a reddish-brown or greenish fluid. It contains pigments (bilirubin and biliverdin), fats and soaps, cholesterol, sodium salts of glycocholic and taurocholic acid, lecithin, and nucleo-albumin furnished by the mucous membrane. There are also present CO₂; chlorides, carbonates, phosphates, and sulphates of the alkalies and of calcium, and iron. The amount normally secreted is from one pint to one and one-half pints in the twenty-four hours.

Surface Relations.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The upper limit of the right lobe of the liver may be defined in the middle line by the junction of the mesosternum with the ensiform cartilage; on the right side the line must be carried upward as far as the fifth rib cartilage in the line of the nipple and then downward to reach the seventh rib at the side of the chest. The upper limit of the left lobe may be defined by continuing this line to the left with an inclination downward to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The lower limit of the liver may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—i.e., the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distention of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—Movable liver or hepatoptosis is a rare condition, in which the liver moves or can be moved from its normal position. It is due to lessened tone of the abdominal
muscules and relaxation of the liver supports. In movable liver the organ may be rotated on its vertical axis or on its transverse axis. Tongue-like lobes have been referred to. On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of wound of the liver from the front, protrusion of a part of this viscous may take place, but can generally easily be replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastro-hepatic omentum and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen. Bleeding is, if possible, arrested by suture ligatures. The edges of a small laceration are simply brought together and sutured by means of a blunt, curved, round needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. If suture fails the actual cautery may succeed. When the laceration is extensive, the liver is sutured to the abdominal wall to hold it firm when pressure is applied, and then the laceration is packed with a piece of iodoform gauze, the end of which is allowed to hang out of the external wound. Abscess of the liver is of not infrequent occurrence, and may open in many different ways on account of the relations of this viscous to other organs. Thus it may burst into the lung, the pus being coughed up, or into the stomach; the pus perhaps being vomited, it may burst into the colon or into the duodenum, or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavity. Abscesses of the liver require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and unless the peritoneum is adherent, gauze is packed all around the exposed liver surface and the abscess opened, if deeply seated, preferably by the thermocautery. Hydatid cysts are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the tinea echinococcus being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid. Tumors of the liver have recently been subjected to surgical treatment by removal of a portion of the organ. The abdomen is opened and the diseased portion of liver exposed; the circulation is controlled by compressing the portal vein and the hepatic artery in the gastro-hepatic omentum and a wedge-shaped portion of liver containing the tumor removed; the divided vessels are ligated and the cut surfaces brought together and sutured in the manner directed above.

When the gall-bladder or one of its main ducts is ruptured, which may occur independently of laceration of the liver, death usually occurs from peritonitis. If the symptoms have led to the performance of a laparotomy and a small rent is found, it should be sutured; if an extensive opening is found the gall-bladder should be removed. If the cystic duct is torn, its intestinal end must be closed and the gall-bladder removed. In rupture of the other ducts, simply provide for free drainage.

The gall-bladder may become distended with bile in cases of obstruction of its duct or of the common bile-duct, or it may become distended from a collection of gall-stones within its interior, thus forming a large tumor. The swelling due to distension with bile is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve a patient of gall-stones, the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right semi-lunar line, commencing at the costal margin. The peritoneal cavity is opened, and, the tumor having been found, gauze pads are packed around it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, close
the incision in the duct by fine sutures in two layers and employ drainage. After all obstruction has been removed, four courses are open to the surgeon: 1. The wound in the gall-bladder may be at once sewed up, the organ returned into the abdominal cavity, and the external incision closed. 2. The edges of the incision in the gall-bladder may be sutured to the fascia of the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. 3. The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as cholecystenterostomy. 4. The gall-bladder may be completely removed (cholecystectomy). Plan 2 is usually followed. Plan 4 is employed when the coats of the gall-bladder are seriously diseased. Plan 2 is employed in obstruction of the common duct by malignant disease.

If a stone blocks the diverticulum of Vater and if the common bile-duct and the pancreatic duct empty into the diverticulum, it is evident that both ducts will be blocked. It has been demonstrated that in such a case the pressure urging the bile onward is sufficient to overcome the pressure in the pancreatic duct and drive bile into the ducts of the pancreas, the result, perhaps, being disastrous inflammation of the pancreas.

Septic trouble arises more rapidly when a stone is blocked in the duct than when stones merely block the gall-bladder, because the first-named part is richer in lymphatics (Murphy).

**THE PANCREAS (Figs. 958, 959, 960, 961).**

**Dissection.**—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse mesocolon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. 3. By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 553).

The Pancreas (παν-χρέας, all flesh) is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and has been compared to a human or a dog's tongue; it is of reddish-white color. Its right extremity being broad, is called the head. The right half of the head above is continuous with the neck, which connects the head to the main portion of the organ, the body. The neck is a slight constriction or thin part of the gland, placed in front of the portal vein, and connecting the head to the body. The left half of the head is separated from the neck by a notch, the incisura pancreaticus. The body of the gland gradually tapers into an extremity directed to the left, and called the tail. The pancreas is placed transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

The **Right Extremity or Head of the Pancreas** (caput pancreatis) (Fig. 958) is shaped like the head of a hammer, being elongated both above and below; it is flattened from before backward, and conforms to the whole concavity of the duodenum, which is slightly overlapped by it. The anterior surface near its left border exhibits a notch, the incisura pancreaticus, which contains the superior mesenteric vessels. The notch marks the separation of the inferior portion of the head, which is known as the uncinate process of Winslow (processus uncinatus [Winslowii]), which rests, below, upon the inferior portion of the duodenum, and, above, is pushed up back of the upper portion. The lower end of the head is crossed by the transverse colon and its mesocolon. Behind, the head of the pancreas is in relation with the inferior vena cava, the left renal vein, the right crus of the Diaphragm, and the aorta. The common bile-duct descends behind, between the duodenum and pancreas, or in the substance of the gland; and the pan-
creatico-duodenal artery descends in front between the same parts. The head of the pancreas is closely adherent to the duodenum.
The Neck of the Pancreas is about an inch long, and passes upward and forward to the left, having the first part of the duodenum above it, and the termination of the fourth portion below. It lies in front of the commencement of the portal vein, and is grooved on the right by the gastro-duodenal and superior pancreatico-duodenal arteries. The pylorus lies just above it.

The Body (corpus pancreatis) and Tail (cauda pancreatis) of the Pancreas are somewhat prismatic in shape, and have three surfaces: anterior, posterior, and inferior.

The Anterior Surface (facies anterior).—The anterior surface is somewhat concave, and is covered by the posterior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. At its right extremity there is a well-marked prominence, called by His the omental tuberosity (tuber omentale).

The Posterior Surface (facies posterior).—The posterior surface is separated from the vertebral column by the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal capsule, the pillars of the Diaphragm, and the origin of the superior mesenteric artery.

The Inferior Surface (facies inferior) (Fig. 959).—The inferior surface is narrow, and lies upon the duodeno-jejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

The Superior Border (margo superior) (Fig. 959).—The superior border of the body is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences to the right in the omental tuberosity, and is in relation with the coeliac axis, from which the hepatic artery courses to the right just above the gland, while the splenic branch runs in a groove along this border to the left.

The Anterior Border (margo anterior).—The anterior border is the position where the two layers of the transverse mesocolon separate; the one passing upward in front of the anterior surface, the other backward below the inferior surface (Fig. 853).

The lesser end or tail of the pancreas is narrow; it extends to the left as far as the lower part of the inner aspect of the spleen, and its end is directed upward and to the left (Fig. 959).

Birmingham describes the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney
forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upward, forms a partial cap for the wide end of the stomach. An occasional anomaly is a pancreas prolonged in front of the duodenum or actually embracing it (annular pancreas).

**Peritoneal Relations** (Fig. 853).—The transverse mesocolon is attached to the anterior border of the pancreas, from the tail to the neck of the gland, and the two layers of the mesocolon separate. The anterior layer which comes from the lesser peritoneum covers part of the anterior surface and the superior surface; the posterior layer, which comes from the greater omentum, covers the rest of the anterior surface and the inferior surface. The posterior surface is devoid of peritoneum.

There is in front of the head and at the anterior margin a narrow strip of pancreas, which remains uncovered by peritoneum and which corresponds to the cellular tissue of the mesocolon.

The principal excretory duct of the pancreas, called the **pancreatic duct** or **canal of Wirsung** (ductus pancreaticus [Wirsungi]) (Figs. 956, 958, and 960), from its discoverer, extends transversely from left to right through the substance of the pancreas. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it constantly receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning obliquely downward, backward, and to the right, it comes into relation with the common bile-duct, lying to

---

its left side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and usually terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches below the pylorus (Figs. 954, 955, and 957).

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum (Fig. 893). In about one-fifth of the subjects there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the duct of Santorini (ductus pancreaticus accessorius [Santorini]) (Figs. 956, 957, and 960).

The pancreatic duct, near the duodenum, is about the size of an ordinary quill; its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

Structure.—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of cæcal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. They are the secreting end tubules. The narrow ducts which come from the end tubules are lined with flat epithelial cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In the centre of the end tubules flat cells are frequently found. They are continuations into the tubules of the duct epithelium. These cells are known as the centro-acinar cells of Langerhans. The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar or rounded in shape and present two zones: an outer one clear and finely striated next the basement-membrane, and an inner granular one next the lumen. The highly refracting granules are known as zymogen granules. During digestion the granules gradually disappear and the cells become clear. During fasting the granular zone occupies more than one-half of the cell (Szymonowicz). In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells; this is termed the paranucleus, and is believed to be an extension from the nucleus. The connective tissue among the gland tubules and alveoli presents in certain parts collections of cells, which are termed inter-alveolar cell-islets, intertubular cell-masses or islands of Langerhans. Opie points out that they are most common in the splenic end of the pancreas. The cells of the islands are smaller than the secreting cells of the alveoli, and are arranged in layers with intervening spaces. The islands are surrounded by fine connective tissue. The spaces in the islands contain capillaries. There are no ducts in the islands of Langerhans. Their function is to furnish the internal secretion of the pancreas.

Blood-vessels, Lymphatics, and Nerves.—The arteries of the pancreas come from the superior pancreatico-duodenal branch of the gastro-duodenal; the inferior pancreatico-duodenal branch of the superior mesenteric; the inferior pancreatic branch of the superior mesenteric; pancreatic branches of the hepatic and pancreatic branches of the splenic. In a few cases a large artery, the pancreatica magna, accompanies the pancreatic duct. In most cases there is no such vessel. The veins are the anterior pancreatico-duodenal branch of the superior mesenteric; the posterior pancreatico-duodenal branch and other pancreatic branches of the portal; and pancreatic branches of the splenic. The lymphatics arise in a network about the lobules.
Numerous collecting trunks pass to the surface of the pancreas, anastomose with each other, and enter into glands about the pancreas. The splenic glands receive most of the trunks. Others are received by glands along the aorta (Sappey), glands at the origin of the superior mesenteric artery, and glands along the pancreatic-duodenal vessels. The nerves come from the coeliac, superior mesenteric, and splenic plexuses.

The Pancreatic Juice.—The pancreatic juice is a clear, somewhat viscid alkaline liquid. Its specific gravity is about 1.030. The solid matter consists chiefly of proteids, and amounts to about 10 per cent. of a sample of the juice. The juice contains a ferment which breaks up fat, a ferment which converts starch into sugar, a ferment which curdles milk, and a ferment which digests proteid material.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—Of late years our knowledge of the structure, functions, and diseases of the pancreas has been notably increased, and surgeons have begun to operate for certain pancreatic diseases. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cancer of the pancreas may be primary or secondary. Primary sarcoma is very unusual; secondary sarcoma is more common, but cancer is far commoner than either form of sarcoma. Adenoma may also occur. Cases are on record of the successful removal of tumors of the pancreas, but the operations are very dangerous, and are seldom attempted. The pancreas may be the seat of supphilitic or tuberculous disease. As a result of pancreatic injury, there may be effusion into the lesser peritoneal cavity. The lesser cavity becomes distended, and the fluid of this pseudo-cyst may contain pancreatic juice (Jordan Lloyd).

True cysts of the pancreas are occasionally found. Pancreatic cysts may result from blocking of the duct, from epithelial proliferation, from traumatism and hemorrhage, or from hydatid disease. Congenital cysts may occur, and cystic carcinoma is sometimes encountered. Cysts of the pancreas may present in the epigastric region above and to the right of the umbilicus. The fluid in these cysts contains some of the pancreatic secretion. A pancreatic cyst is best treated by opening the abdomen, suturing the cyst to the skin, opening the cyst and providing for drainage. Complete extirpation of the cyst is invariably difficult and is usually impossible. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of diaphragmatic hernia. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of excision of the pylorus great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious and even with fatal results, peritonitis and fat necrosis, and gangrene being caused.

Rupture of the pancreas as a solitary result of traumatism is very unusual, but is more common in violent injuries which rupture the liver and spleen as well. An injury which lacerates the pancreas and permits blood and pancreatic juice to flow into the lesser peritoneal cavity is usually rapidly fatal, but may not be. The foramen of Winslow may be occluded by inflammation, and a pseudo-cyst may form. In severe laceration of the pancreas alone, it would be proper to open the abdomen, ligature bleeding vessels, suture the pancreas, and drain the lesser peritoneal cavity posteriorly. A gunshot wound of the pancreas requires posterior drainage. Every effort must be made in a pancreatic wound to rapidly get rid of pancreatic fluid by drainage from the wound area, as this fluid is extremely irritant and may cause gangrene.

Inflammation of the pancreas is due to infection. Occasionally it seems to follow the entrance of bile into the pancreatic duct, because of plugging of the ampulla with a calculus (Halsted, Opie). Hemorrhage into the pancreas is frequent in acute pancreatitis, and fat necrosis is common in the fat of the mesentery, subperitoneal tissue, omentum, and other parts. Acute pancreatitis may be recovered from if the abdomen is opened, the pancreas incised, and drainage employed.

In chronic interstitial pancreatitis of the head of the pancreas the gall-duct is apt to become blocked, and the disease is frequently mistaken for cancer. Cure may follow opening and drainage of the gall-bladder.

THE SPLEEN (LIEN) (Figs. 958. 959, 961).

The spleen belongs to that class of bodies which are known as ductless glands. It is probably related to the blood-vascular system, but in consequence of its

1 Poirier, Cunéo, and Delamarre on the Lymphatics. Edited and translated by Cecil H. Leaf.
2 Robson and Moynihan on Diseases of the Pancreas.
anatomical relationship to the stomach and its physiological relationship to the liver it is convenient to describe it in this section. It is situated principally in the posterior portion of the left hypochondriac region, its upper and inner extremity extending into the epigastric region; lying between the fundus of the stomach and the Diaphragm. If the abdomen is opened a spleen of ordinary size is not visible from the front, as it is placed between the left kidney, Diaphragm, and stomach. It moves with the respiratory movements and with the movements of the stomach. It is the largest of the so-called ductless glands, and varies greatly in size. Usually it measures some five inches in length. It is of an oblong, flattened form, soft, of very brittle consistence, highly vascular, and of a dark-purplish color.

**Surfaces.** The External or Phrenic Surface (*facies diaphragmatica*).—The external or phrenic surface is convex, smooth, and is directed upward, backward, and to the left, except at its upper end, where it is directed slightly inward. It is in relation with the under surface of the Diaphragm, which separates it from the eighth, ninth, tenth, and eleventh ribs of the left side, and in part from the lower border of the left lung and pleura. It is to be remembered that not only are the peritoneum and the Diaphragm between the spleen and the ribs, but also the cavity of the left pleura and a portion of the left lung.

The Internal Surface.—The internal surface is concave, and divided by a ridge into an anterior or larger, and a posterior or smaller portion.

The Anterior Portion of the internal surface or the gastric surface (*facies gastrica*), which is directed forward and inward, is broad and concave, and is in contact with the posterior wall of the great end of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the hilum (*hilus lienalis*). This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The Posterior Portion of the internal surface or the renal surface (*facies renalis*) is directed inward and downward. It is somewhat flattened, does not reach as high as the gastric surface, is considerably narrower than the latter, and is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal capsule.

The upper end of the spleen (*extremitas superior*) is directed inward, toward the vertebral column, where it lies on a level with the eleventh dorsal vertebra. The lower end (*extremitas inferior*), sometimes termed the basal surface, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and is generally in contact with the tail of the pancreas. The anterior border (*margo anterior*) is free, sharp, and thin, and is often notched, especially below. It separates the phrenic surface from the gastric surface. The posterior border (*margo posterior*) is more rounded and blunter than the anterior. It separates the renal portion of the internal surface from the phrenic surface. It corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney.
The **internal border** is the name sometimes given to the ridge which separates the renal and gastric portions of the internal surface.

The spleen is surrounded by peritoneum, except at the hilum and the serous membrane, is firmly adherent to its capsule, and is held in position by two folds of this membrane: one, the **lienorenal ligament** (*ligamentum phrenicocolicium*) (Figs. 857 and 860), is derived from the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen. Between its two layers the splenic vessels pass; the second, the **gastro-splenic omentum** (*ligamentum gastrolienale*), also formed of two layers, derived from the greater and lesser sacs, respectively, where they meet between the spleen and stomach (Fig. 860). Between these two layers run the vasa brevia of the splenic artery and vein. The spleen is also supported by the **phreno-colic ligament** (*ligamentum phrenicocolicum*), upon which its lower end rests.

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually about five inches in length, three inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350; while in the adult it varies from 1 to 320 to 1 to 400. *In old age*, the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from eighteen to twenty pounds.

Frequently in the neighborhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated, or connected to the spleen by thin bands of splenic tissue. Every such nodule is known as a **supernumerary** or **accessory spleen** (*lien accessorius*). Accessory spleens vary in size from that of a pea to that of a plum.

---

**Fig. 963.**—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.
Support and Movability of the Spleen.—The spleen is normally movable within certain narrow limits. It moves with respiration and with stomach movements. It is supported by ligaments (p. 1355). An unduly movable spleen is called a movable spleen. In order that a spleen shall become unduly movable, the ligaments must stretch, and this stretching is often effected when the organ is greatly enlarged, but even an apparently normal spleen may become movable. Movable spleen is usually associated with movable left kidney.

Structure.—The spleen is invested by two coats—an external serous and an internal fibro-elastic coat.

The External or Serous Coat (tunica serosa).—The external or serous coat is derived from the peritoneum; it is thin, smooth, and in the human subject is intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The Fibro-elastic Coat (tunica albuginea).—The fibro-elastic coat forms the framework of the spleen. It is composed of connective tissue containing muscle-cells and elastic fibres, and it invests the organ as a capsule, and at the hilum is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, trabeculae (trabeculae lienis) (Figs. 963 and 964), are given off in all directions; these uniting, constitute the framework of the spleen. This framework resembles a sponge-like material, consisting of a number of small spaces or areolae formed by the trabeculae, which are given off from the inner surface of the capsule, or from the sheaths prolonged inwardly on the blood-vessels. The spaces or areolae contain the adenoid material known as splenic pulp (pulpa lienis).

The proper coat, the sheaths of the vessels and the trabeculae, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter decidedly predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre, and in some mammalia (e.g., dog, pig, and cat) a very considerable amount, so that the trabeculae appear to consist chiefly of muscular tissue. It is probably because of this muscular structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The proper substance of the spleen or splenic-pulp is a soft mass of a dark reddish-brown color, resembling grumous blood. When a thin section is examined under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the sustentacular or supporting cells of the pulp. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolae formed by the trabeculae of the capsule; so that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not stain deeply with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess ameboid movements (Cohnheim). In many of them may be seen deep red or reddish-yellow granules of various sizes which present the characters of the haematin of the blood. Sometimes, also, uncharged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes
these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolæ formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles, the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

Blood-vessels of the Spleen.—The splenic artery (Fig. 961) is remarkable for its large size in proportion to the size of the organs, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance, receiving sheaths from the involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells (Figs. 964, 965, and 966). Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The arterioles (Fig. 966), supported by the minute trabeculae, traverse the pulp in all directions in bundles or pencilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material.1 This change is effected by the conversion of the connective tissue into a lymphoid tissue, the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are

---

1 According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a "solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath." (Atlas of Histology, p. 424.)
in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue (Fig. 966), presents here and there thickenings of a spheroidal shape, the Malpighian bodies of the spleen (noduli lymphatici lienales [Malpighii]) (Fig. 965). These bodies vary in size from about the $\frac{1}{100}$ of an inch to the $\frac{1}{2}$ of an inch in diameter. They are merely local expansions or hyperplasies of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than on the other, and that, therefore, in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells.

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amoeboid movements, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions; their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered; presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 966). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins (Fig. 963), which commence much in the same way as the arteries terminate. Where a vein is about to originate the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillae arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform endothelial cells which are
continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from six or more branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the portal vein (Figs. 958 and 962).

The veins are remarkable for their numerous anastomoses, while the arteries hardly Anastomose at all.

The lymphatics originate in two ways—i.e., from the sheaths of the arteries and in the trabecula. The former trunks are the deep collecting trunks, and accompany the blood-vessels; the latter pass to the superficial lymphatic plexus, which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. The deep trunks at the hilum number from five to ten, and terminate in the splenic glands. The superficial trunks also pass to the hilum and terminate in the splenic glands.

The nerves are derived from the splenic plexus, which is part of or connected with the solar plexus. The nerves enter the spleen with the vessels.

**Surface Form.**—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the eighth, ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions—viz., from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid-axillary line" (Quain).

**Surgical Anatomy.**—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hemorrhage, owing to the extreme vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and thus antagonizes the escape of blood. In cases in which the symptoms suggest such an injury and indicate danger to life, laparotomy must be performed; and if the hemorrhage cannot be arrested by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this dislocation may render necessary removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, leukemia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood disease. In these cases the mass may fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.
The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease. In movable spleen, if the organ is normal, follow the advice of Rydygier and loosen the parietal peritoneum to make a pocket, place the spleen in the pocket, and pass sutures through the parietal peritoneum and the splenic ligaments. A movable diseased spleen should be removed.

Extirpation of the spleen has been performed for wounds or injuries, floating spleen, simple hypertrophy, and leukæmic enlargement; but in the latter case the operation is now regarded as unjustifiable, as it is practically certain to terminate fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein and which inevitably induces grave shock. In applying the ligatures the surgeon must not include the tail of the pancreas, and in lifting out the organ care must be taken to avoid rupturing the capsule.
THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

The larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and forepart of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebrae, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of the epiglottis was a little above the level of the cartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral disks. The movements of the head affect the position of the larynx. When the head is drawn back, the larynx is lifted, and when the chin approaches the chest the larynx is depressed. During swallowing the larynx moves distinctly; during singing it moves slightly. The larynx is suspended by the stylo-hyoid ligament, the

---

Fig. 967.—Sagittal section of a man twenty-one years of age. (After W. Braune.)
muscles of the upper border of the hyoid bone, the Stylo-pharyngeus and Palato-pharyngeus muscles. According to Sappey, the average measurements of the adult larynx are as follows:

<table>

</tbody>
</table>

Until puberty there is no marked difference between the larynx of the male and that of the female. In the latter its further increase in size is only slight, whereas in the former it is great; all the cartilages are enlarged, and the thyroid becomes prominent as the pomum Adami in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea.

In the median line of the neck the larynx has in front of it the skin and cervical fascia. There is often a bursa between the skin and fascia over the most prominent part of the larynx. It is called the bursa subcutanea prominentiae laryngeae. It is present particularly in men, and is seldom found in the young or in women. The larynx is covered to each side by the thyroid gland, and the Sterno-hyoid, Sterno-thyroid, Thyro-hyoid, and Omo-hyoid muscles, and the Inferior constrictors of the pharynx. Posterior is the laryngeal portion of the pharynx.

The Cartilages of the Larynx (cartilagines laryngis).—The cartilages of the larynx are nine in number, three single, and three pairs:

- Thyroid.
- Cricoid.
- Epiglottis.
- Two Arytenoid.
- Two Cornicula Laryngis.
- Two Cuneiform.

The Thyroid Cartilage (cartilago thyroideae) (Figs. 968 and 969).—The thyroid cartilage (from θυρός, a shield) is hyaline cartilage and is the largest cartilage of the larynx. It is at the anterior and upper portion of the larynx. It consists of two lateral lamellae or alae, united at an acute angle in front, forming a vertical projection in the middle line, which is prominent above and called the pomum Adami (prominentia laryngea). This projection is subcutaneous, is more distinct in the male than in the female, and is often separated from the integument by a bursa, the bursa subcutanea prominentiae laryngeae.

Each lamella is quadrilateral in form. Its outer surface (Fig. 968) presents an oblique ridge (linea obliqua), which passes downward and forward from a tubercle situated near the root of the superior cornu, the superior tubercle (tuberculum thyroideum superioris), to a small tubercle near the anterior part of the lower border, the inferior tubercle (tuberculum thyroideum inferius). This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border gives attachment to part of the Inferior constrictor muscle. Just below each superior tubercle there is often an opening, the thyroid foramen (foramen thyroideum).

The anterior borders of the alae of the thyroid cartilage which are continuous below are separated above by a V-shaped notch, the thyroid notch (incisura thyroidea [superior]).
The Inner Surface (Fig. 969) of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles, and the thyro-epiglottidean ligament.

The Upper Border or Margin of the Thyroid Cartilage (Fig. 969) is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of the thyroid notch, in the middle line, immediately above the pomum Adami. This border gives attachment throughout its whole extent to the thyro-hyoid or hyothyroid membrane (membrana hyothyreoidea).

The Lower Border or Margin (Fig. 969) is nearly straight in front, but behind, close to the cornu, it is concave. It is connected to the cricoid cartilage, in and near the median line, by the middle portion of the crico-thyroid membrane (membrana cricothyreoidea); and, on either side, by the Crico-thyroid muscle.

The Posterior Borders (Fig. 969) are thick and rounded, and each terminates above, in a superior cornu (cornu superius), and below, in an inferior cornu (cornu inferior). The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in conical extremities, which give attachment to the lateral thyro-hyoid ligaments. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and each presents on its inner surfaces a small oval articular facet for articulation with the side of the cricoid cartilage (Fig. 968). The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

During infancy the alae of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the intrathyroid cartilage. This strip extends from the upper to the lower border of the thyroid cartilage in the middle line, and is distinguished from the alae by being more transparent and more flexible.

The Cricoid Cartilage (cartilago cricoidea) (Figs. 968, 969, and 971).—The cricoid cartilage is so called from its resemblance to a signet ring (χρίζων, a ring). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It is hyaline cartilage and consists of two parts: a quadrato portion, situated behind, and a narrow ring or arch, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

Its Posterior Portion or Lamina (lamina cartilaginis cricoideae) is very deep and broad, and measures from above downward about an inch (2 to 3 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the oesophagus; and on either side a broad depression for the Crico-arytenoideus posticus muscle.

Its Anterior Portion or Arcus (arcus cartilaginis cricoideae) is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (5 to 7 cm.); it affords attachment externally in front and at the sides to the Crico-thyroid muscles, and, behind, to part of the Inferior constrictor.
At the point of junction of the posterior quadrato portion with the rest of the cartilage is a small round elevation, for articulation with the inferior cornu of the thyroid cartilage.

The **Lower Border** of the cricoid cartilage is horizontal, and connected to the upper ring of the trachea by fibrous membrane (Figs. 968 and 970).

Its **Upper Border** is directed obliquely upward and backward, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the crico-thyroid membrane; at the sides, to the lateral portion of the same membrane and to the lateral Crico-arytenoid muscle; behind, it presents, in the middle, a shallow notch, and on each side of this is a smooth, oval surface, directed upward and outward, for articulation with the arytenoid cartilage.

The **Inner Surface** of the cricoid cartilage is smooth, and lined with mucous membrane.

The **Arytenoid Cartilages** (cartilagines arytaenoideae) (Figs. 969, 972, and 976).—The arytenoid cartilages are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (ἀργύτασα, a pitcher). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx in the interval between the posterior borders of the alae of the thyroid cartilages. Each cartilage is in form a three-sided pyramid, and presents for examination **three surfaces**, a **base**, and an **apex**.

The **Posterior Surface** is triangular, smooth, concave, and gives attachment to the transverse portion of the Arytenoid muscle.

The **Anterior** or **External Surface** is somewhat convex and rough. It presents, near its apex, a small elevation, the **collicus**; from this a **ridge** (crista arcuata) passes backward and then forward and downward into a sharp-pointed process, the **vocal process**. This ridge separates a deep depression above, the **fovea triangularis**, from a broader and shallower depression below, the **fovea oblonga**. A short distance above the base a small tubercle gives origin to the ligament of the false vocal cord, the superior thyro-arytenoid ligament. To the outer part of the ridge, as well as the surface above and below, is attached the Thyro-arytenoid muscle.

The **Internal Surface** is narrow, smooth, and flattened, covered by mucous membrane, and forms the lateral boundary of the respiratory part of the glottis.
The **Base** (*basis*) of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: the **external angle**, which is short, rounded, and prominent, projects backward and outward, and is termed the **muscular process** (*processus muscularis*), from receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The **anterior angle**, also prominent, but more pointed, projects horizontally forward, and gives attachment to the inferior thyro-arytenoid ligament, the supporting ligation of the true vocal cord. This angle is called the **vocal process** (*processus vocalis*).

The **Apex** of each cartilage is pointed, curved backward and inward, and surmounted by a small conical, cartilaginous-nodule, the **corniculum laryngis**, articulated with or united to the arytenoid cartilage.

The **Cornicula Laryngis or Cartilages of Santorini** (*cartilagines corniculatae*) (Figs. 969 and 975).—The cornicula laryngis are two small conical nodules, consisting of white fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The **Cuneiform Cartilages or Cartilages of Wrisberg** (*cartilagines cuneiformes*) (Figs. 969 and 971).—The cuneiform cartilages are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis, and is called the aryteno-epiglottidean fold (*plica arypepiglottica*) (Fig. 971); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **Epiglottis or the Cartilage of the Epiglottis** (*cartilago epiglottica*) (Figs. 967, 969, 970, 971, 972, and 975).—The epiglottis is a thin, flexible lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue in front of the superior opening of the larynx. Its free extremity, which is directed upward, is broad and rounded, and often notched; its attached part (*petiolus epiglottidis*) is long, narrow, and connected to the receding angle between the alae of the thyroid cartilage, just below the median notch, by a long, narrow ligamentous band, the **thyro-epiglottic ligament** (*ligamentum thyroepiglotticum*) (Fig. 972). It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the **hyo-epiglottic ligament** (*ligamentum hyoepiglotticum*).

Its **Anterior** or **Lingual Surface** is curved forward, toward the tongue, and covered at its upper, free part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the **glosso-epiglottidean folds** (*plicae glossoepiglotticae*) (Fig. 971). The **median glosso-epiglottidean fold** (*plica glossoepiglottica mediana*) contains the elastic glosso-epiglottic ligament (*ligamentum glossoepiglotticum*). Each **lateral glosso-epiglottidean fold** (*plica glossoepiglottica lateralis*) runs from the front and side of the base of the epiglottis to the side of the tongue. The depression between the epiglottis and the base of the tongue on each side of the median fold is named the **vallecula epiglottica**. The lower part of the anterior surface of the epiglottis lies behind the hyoid bone, the thyro-hyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

Its **Posterior** or **Laryngeal Surface** is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the **tubercle or cushion** (*tuberculum epiglotticum*) (Fig. 970); when the mucous membrane is removed, the surface of the cartilage is seen to be studded with a number of small mucous glands, which are lodged in little pits upon its surface. To its sides the **aryteno-epiglottidean folds** (*plicae arypepiglotticae*) are attached (Fig. 971).

**Structure.**—The cuneiform cartilages, the epiglottis, and the apices of the arytenoids are composed of yellow elastic cartilage, which shows little tendency to calcification; on the other hand, the thyroid, cricoid, and the greater part of the
arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone. The cornicula laryngis consist of white fibro-cartilage, which becomes osseous about the seventieth year.

Ligaments, Joints, and Membranes of the Larynx.—The ligaments of the larynx are extrinsic—i.e., those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and intrinsic, those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The Thyro-hyoid or Hyo-thyroid Membrane or Ligament (membrana hyothyreoida) (Fig. 972) is a broad, fibro-elastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the posterior border of the body and greater cornua of the hyoid bone, passing behind the postero-inferior surface of the hyoid, and being separated from this surface by a synovial bursa (bursa m. sternohyoidi), which facilitates the upward movement of the larynx during deglutition. The membrane is thicker in the middle line than at either side. This thickening is due to elastic fibres, and constitutes the middle thyro-hyoid ligament (ligamentum hyothyreoidenum medium). On each side the posterior extremity of the membrane is thickened by elastic fibres, constituting the lateral thyro-hyoid ligament (ligamentum hyothyreoidenum laterale). The thyro-hyoid membrane is pierced on each side by the superior laryngeal vessels and the internal laryngeal nerve. The anterior surface of the thyro-hyoid membrane is in relation with the Thyro-hyoid, Sterno-hyoid, and Omo-hyoid muscles and with the body of the hyoid bone. The two lateral ligaments are rounded, elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (cartilago triticea), sometimes bony, is frequently found in each.

The Membrana Quadrangularis is an elastic membrane containing numerous glands. The fibres of the membrane run in part downward and in part downward and backward. The membrane on each side arises in front and above at the lateral margin of the cartilage of the epiglottis, below at the posterior surface of the angle of the thyroid cartilage and becomes attached behind to the cornicula laryngis and to the inner margins of the arytenoid cartilages. The membranes converge below and medianward. The ligamentum ventriculare is the superior end of the membrane (Spalteholz). The fibres constituting the ligamentum ventriculare are given off at the thyroid cartilage above the ligamentum vocale and pass horizontally backward to the medial margin of the fovea triangularis of the arytenoid cartilage. The epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The Glosso-epiglottidean Folds or Ligaments (plicae epiglotticae) (Fig. 971) number three. The middle glosso-epiglottidean fold (plica glossoepiglottica mediana) passes from the middle of the anterior free surface of the epiglottis to the base of the tongue. It contains the glosso-epiglottic ligament. The lateral glosso-epiglottidean or the pharyngo-epiglottidean fold (plica glossoepiglottica lateralis) on each side passes from the side of the epiglottis to the side of the base of the tongue and to the pharyngeal wall. On each side between the median and lateral folds is a depression, the vallecula epiglottica.

The Hyo-epiglottic Ligament ((ligamentum hyoepiglotticum) is an elastic band, which extends from the anterior surface of the epiglottis, near its apex, to the

upper border of the body of the hyoid bone. The epiglottis is attached to the thyroid cartilage, below and behind the superior thyroid notch, by the strong and elastic thyro-epiglottic ligament (ligamentum thyroepiglotticum) (Fig. 972). Between the epiglottis, the hyo-epiglottic ligament and the thyro-hyoid membrane is a triangular space containing fat on each side of the median line.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the crico-thyroid membrane and the capsular ligaments. The crico-thyroid Membrane (conus elasticus) (Figs. 968 and 975) is an elastic membrane which passes radially from the posterior surface of the angle of the thyroid cartilage to the upper margin of the arch of the cricoid cartilage and to the vocal processes of the arytenoid cartilages. It is composed mainly of yellow elastic tissue. It consists of three parts, a central triangular portion and two lateral portions. The central part (ligamentum cricothyroideum medium) is thick and strong, narrow above and broadening out below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the Crico-thyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two crico-thyroid arteries. The lateral portions are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords with which they are continuous. On each side are the uppermost fibres from the inferior thyro-arytenoid ligament (ligamentum vocale).

The lateral portions are lined internally by mucous membrane, and are separated from the thyroid cartilage by the lateral Crico-arytenoid and Thyro-arytenoid muscles. This membrane and the muscles just mentioned reduce greatly the interior of the larynx. The crico-thyroid membrane with the membrana quadrangularis constitute the membrana elastica laryngis.

The Crico-thyroid Articulation (articulatio cricothyreoida) (Fig. 968), on each side of the inferior cornu of the thyroid, with the cricoid cartilage on each side. A loose synovial membrane (capsula articularis cricothyreoida) encloses the articulation.

The synovial capsule is strengthened by the ligamenta ceratocricoidae, which pass from the lesser cornu of the thyroid to the lamina of the cricoid cartilage.

The Crico-arytenoid Articulation (articulatio cricoaryteneoidea) (Fig. 969) on each side is between the articular surface of the arytenoid cartilage and the arytenoid articular surface of the cricoid cartilage.

The ligaments connecting the arytenoid cartilages to the cricoid are on each side a capsular ligament (capsula articularis cricoaryteneoidea) and a posterior crico-arytenoid ligament (ligamentum cricoaryteneoideum posterius). The capsular ligaments are thin and loose capsules attached to the margin of the articular
surfaces; they are lined internally by synovial membrane. The posterior crico-arytenoid ligaments extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The Crico-tracheal Ligament (ligamentum cricotracheale) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each side.

There is on each side an articulation between the arytenoid cartilage and the cartilage of Santorini (synchondrosis arycorniculada). The cartilage of Santorini is somewhat movable and is fixed to the arytenoid by lax connective tissue. From each cartilage of Santorini a band of connective tissue runs down to the lamina of the cricoid cartilage and to the pharyngeal mucous membrane. Beneath the arytenoid muscles the ligaments from the two sides join and pass down together. Thus is formed a Y-shaped ligament called the ligamentum corniculopharyngeum. The portion between the cricoid cartilage and the mucous membrane of the pharynx is sometimes called the ligamentum cricopharyngeum.

Interior of the Larynx (Figs. 970, 971, and 972).—The cavity of the larynx (cavum laryngis) extends from the superior aperture of the larynx to the lower border of the cricoid cartilage. It is divided into two parts by the projection inward of the true vocal cords, between which is a narrow triangular fissure or chink, the rima glottidis. It is further subdivided by the false vocal cords. So we consider the larynx as divided into a portion above the false cords, a portion between the false and true vocal cords, and a portion below the true cords. The entrance of the first compartment is the superior aperture of the larynx.

The Superior Aperture of the Larynx (aditus laryngis).—The superior aperture of the larynx (Figs. 970 and 971) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages and the cornicula laryngis; and laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apices of the arytenoid cartilages; these are the aryteno-epiglottidean folds (Figs. 971 and 972), on the margins of which the cuneiform cartilages form more or less distinct whitish prominences.

The small gap between the cartilages of Santorini is called the incisura inter-arytaenoidea. On the pharynx, on either side of the posterior portion of the superior aperture of the larynx, is a recess, called the sinus pyriformis.

Upper Compartment or Vestibule of the Laryngeal Cavity (vestibulum laryngis) (Figs. 970 and 972).—The vestibule is the portion between the superior opening and the false vocal cords. It is much narrower below than above. It is bounded anteriorly by the mucous membrane-covered epiglottis. The lower part of the epiglottis exhibits a prominence called the cushion or tubercle (tuberculum epiglotticum) (Fig. 970). The lateral wall of the vestibule on each side is the aryteno-epiglottidean fold (plica aryepiglottica) (Fig. 972), which extends from the summit of the arytenoid cartilage forward, upward, and outward to the margin of the epiglottis, and which contains fibres of the Thyro-epiglottideus and Arytenoideus muscles (musculus arytaenoepiglottidean). Near the posterior end of the fold are two trivial elevations: the anterior elevation is caused by the prominence of the cuneiform cartilage, and is called the cuneiform tubercle of Wrisberg (tuberculum cuneiforme [Wrisbergi]); the posterior elevation is caused by the anterior margin of the arytenoid cartilage and the cartilage of Santorini, and is called the cornical tubercle of Santorini (tuberculum corniculatum [Santorini]). Between these elevations is a groove, the filtrum ventriculi of Merkel, which passes into the space between the false and true vocal cords. The anterior elevation passes into the false vocal cord, the posterior elevation into the true vocal cord. The posterior portion of the laryngeal vestibule is the narrow space between the upper portions of the arytenoid cartilages.
The Middle Compartment of the Larynx (Figs. 970 and 972).—This lies between the false vocal cords above and the true vocal cords below. It is the smallest of the laryngeal compartments. It opens into the vestibule by the way of the gap between the false vocal cords, which is called the false glottis; it opens into the lower compartment of the larynx by way of the space between the true vocal cords, the true glottis.

The True Glottis.—The true glottis is the apparatus for producing tone and is formed by the true vocal cords.

The Chink of the Glottis (rima glottidis) (Figs. 970 and 971).—The chink of the glottis is the elongated fissure or chink between the inferior or true vocal cords in front, and between the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into an anterior, interligamentous or vocal portion, the glottis vocalis (pars intermembranacea), and a posterior, intercartilaginous or respiratory portion, the glottis respiratoria (pars intercartilaginea). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The vocal portion averages about three-fifths of the length of the entire aperture. It is the narrowest part of the cavity of the larynx, and its level corresponds to the bases of the arytenoid cartilages. Its length, in the male, measures rather less than an inch (20 to 25 mm.); in the female it is shorter by 5 or 6 mm., or three lines. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest—i.e., when these structures are uninfluenced by muscular action, as in quiet respiration, the glottis vocalis is triangular, with its apex in front and its base behind, the latter being represented by a line about 8 mm. long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the glottis respiratoria is rectangular. During extreme adduction of the cords, as in the emission of a high note, the glottis vocalis is reduced to a linear slit by the apposition of the cords, while the glottis respiratoria is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outward, and the glottis respiratoria is triangular in shape, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the glottis vocalis diverging from before backward, those of the glottis
respiratoria diverging from behind forward, the widest part of the aperture corresponding with the attachment of the cords to the vocal processes.¹

The **Superior or False Vocal Cords** (*plicae ventriculares*) (Figs. 970, 971, and 972), so called because they are not directly concerned in the production of the voice. Each is a thick fold of mucous membrane, enclosing a narrow band of fibrous tissue, the **superior thyro-arytenoid ligament** (*ligamentum ventriculare*), which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx. The false vocal cord contains the lower part of the membrana quadrangularis with the ligamentum ventriculare, the muscle ventricularis and laryngeal glands.

The **Inferior or True Vocal Cords** (*plicae vocales*) (Figs. 970, 971, 972, and 976), so called from their being concerned in the production of sound. Each is a strong band, the **inferior thyro-arytenoid ligament** (*ligamentum vocale*), covered on its surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the alae of the thyroid cartilage, and behind to the anterior angle of the base of the arytenoid. This angle is called the **vocal process**. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely pale, thin, and closely adherent to its surface. The upper margin of the true vocal cord is covered with mucous membrane, and is the lower boundary of the ventricle of the larynx. Over the vocal process it is yellowish (*macula flava*). The true vocal cord contains the upper part of the crico-thyroid membrane with the ligamentum vocale and the muscle vocalis.

¹ On the shape of the rima glottidis, in the various conditions of breathing and speaking, see Czermak, On the Laryngoscope, translated for the New Sydenham Society.—En. of 15th English edition.
The Ventricle of the Larynx or Laryngeal Sinus (ventriculus laryngis [Morgagnii]) (Figs. 970 and 972) is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the superior vocal cord; below, by the straight margin of the inferior vocal cord; externally, by the mucous membrane covering the corresponding Thyro-arytenoides muscle. The anterior part of the ventricle leads up by a narrow opening into a caecal pouch of mucous membrane of variable size, called the laryngeal pouch.

The Laryngeal Sacculus or Pouch (appendix ventriculi) (Fig. 970), or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament; its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (compressor sacculi laryngis of Hilton); while its exterior is covered by the Thyro-arytenoides and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis, and discharge the secretion it contains upon the vocal cords, the surfaces of which it is intended to lubricate.

![Fig. 973.—Muscles of larynx, front view. The sterno-thyroids and right thyro-hyoid have been removed. (Testut.)](image)

![Fig. 974.—Muscles of larynx, from behind. (Testut.)](image)

The Lower Compartment of the Larynx (Figs. 970 and 972).—This space is just beneath the true vocal cords and leads into the trachea. It is called the additus glottidis inferior. Above, on cross-section, it is oval; below, it is round. It is bounded by the inner surface of the crico-thyroid membrane and the cricoid cartilage.

Muscles of the Larynx (musculi laryngis).—We do not consider all muscles which are attached to laryngeal cartilages as laryngeal muscles. Some muscles so attached in reality belong to other regions, for instance, the Inferior constrictor, the Stylo-pharyngeus, the Sterno-thyroid, the Thyro-hyoid, and the Palatopharyngeus. The muscles which really belong to the larynx are called intrinsic.

Four muscles of the vocal cords and rima glottidis are paired and one is single.
The paired muscles are the crico-thyroid, the posterior crico-arytenoid, the lateral crico-arytenoid, and the thyro-arytenoid. The single muscle is the arytenoideus.

A Crico-thyroid (m. cricothyreoideus) (Figs. 968, 970, and 973) is placed on each side. It is triangular in form, and situated at the forepart and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornu.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the central part of the crico-thyroid membrane.

The Posterior Crico-arytenoid (m. cricoarytaenoideus posterior) (Figs. 974, 975, and 976), a paired muscle, arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the outer angle (muscu-

lar process) of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.\(^1\)

The Arytenoideus (Figs. 972, 974, 975, and 976) is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The oblique fibres (m. arytaenoideus obliquus), the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one. The transverse fibres (m. arytaenoideus transversus), the deepest and most numerous, pass transversely across between the two cartilages; hence the Arytenoideus was formerly considered as three muscles, the trans-

\(^1\) Merkel, of Leipzig, has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the "Muscus kerato-cricoideus." It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir William Turner (Edinburgh Medical Journal, February, 1890) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backward and downward, opposing in some measure the part of the Cricothyroid muscle, which is connected to the anterior margin of the horn.—Ed. of 15th English edition.
verse and the two oblique. A few of the oblique fibres are around the outer margin of the cartilage, and blend with the Thyro-arytenoid in the aryteno-epiglottidean fold, and are called the Aryteno-epiglottideus muscles.

In order to expose the rest of the muscles of the larynx the thyroid cartilage of one side must be removed. Begin by taking away the crico-thyroid muscle, then dividing the lateral thyro-hyoid ligament; disarticulate the inferior cornu of the thyroid cartilage from the cricoid cartilage, then carefully cut through the thyroid cartilage a short distance from its union with its twin. The following muscles will then be exposed after a little cleaning: the Lateral crico-arytenoid, the Thyro-arytenoid, the Thyro-epiglottideus.

The Lateral crico-arytenoid (m. cricoarytenoides lateralis) (Figs. 975 and 976), a paired muscle, is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoïd cartilage, and, passing obliquely upward and backward, is inserted into the muscular process of the arytenoid cartilage in front of the posterior crico-arytenoid muscle.

The Thyro-arytenoid (m. thyroarytenoides) (Figs. 975 and 976), a paired muscle, is broad and flat. It lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane. Its fibres pass backward and outward, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi. The inner or inferior fasciculus (m. vocalis), the thicker, is prismatic in shape and is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. This fasciculus on its deeper surface gives off some fibres which are attached to the true vocal cord. These are called the ary-vocalis (Ludwig). The outer or superior fasciculus, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.

The muscles of the epiglottis are the—

The Thyro-epiglottideus (m. thyroepiglotticus) is a delicate fasciculus, which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, of which it is sometimes described as a part, and spreads over the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottidean fold, while the others are continued forward to the margin of the epiglottis.

The Aryteno-epiglottideus (Figs. 970 and 975) is properly divided into two muscles, a superior and an inferior.

The Aryteno-epiglottideus superior consists of a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilages, and become lost in the fold of mucous membrane, the aryteno-epiglottidean fold, extending between the arytenoid cartilage and the side of the epiglottis.

The Aryteno-epiglottideus inferior, the Compressor sacculi laryngis of Hilton, arises from the arytenoid cartilage, just above the attachment of the superior vocal cord; passing forward and upward, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.

1 Henle describes these two portions as separate muscles, under the names of the External and Internal thyro-arytenoid.—Ed. of 15th English edition.

2 Luschka has described a small but fairly constant muscle as the Arytenoideus rectus. It is attached below to the posterior con cave surface of the arytenoid cartilage, beneath the Arytenoideus muscle, and, passing upward, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini (Anatomy, by Hyrtl, p. 718).—Ed. of 15th English edition.

3 Musculus turricephalus. Boehsledt Jr. (Prager Vierteljahrschrift, 1896, 2d part) describes a muscle hitherto entirely overlooked, except by Henle, who makes a brief statement in his Anatomy, which arises from the nodule of cartilage (corpus triticeum) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the Hyo-glossus muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.—Ed. of 15th English edition.
Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the two Posterior crico-arytenoids; and those which close it are the Arytenoideus and the two Lateral crico-arytenoids.

2. The muscles which regulate the tension of the vocal cords are the two Cricothyroids, which tense and elongate them, and the two Thyro-arytenoids, which relax and shorten them. The Thyro-epiglottideus is a depressor of the epiglottis, and the Aryteno-epiglottideus, superior and inferior, constrict the superior aperture of the larynx.

The Posterior crico-arytenoids separate the chordae vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their vocal processes and the vocal cords attached to them become widely separated.

The Lateral crico-arytenoids close the glottis by rotating the arytenoid cartilages inward so as to approximate their vocal processes.

The Arytenoideus muscle approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The Crico-thyroid muscles produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by its extrinsic muscles; then the Crico-thyroid muscles, when they act, draw upward the front of the cricoid cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The Thyro-arytenoid muscles, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords.

But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The Thyro-epiglottidei may depress the epiglottis; they assist in compressing the sacculi laryngis. The Aryteno-epiglottideus superior constricts the superior aperture of the larynx, when it is drawn upward, during deglutition. The aryteno-epiglottideus inferior, together with some fibres of the Thyro-arytenoidi, compress the sacculus laryngis.

The Mucous Membrane of the Larynx is continuous above with that lining the mouth and pharynx, and it is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the anterior part of the upper surface of the epiglottis, to which it is closely adherent. In the rest of the larynx, above the true vocal cords, it is lax and rests upon a considerable submucous layer. The mucous membrane, with the submucous coat, ligamentous and muscular fibres, forms the aryteno-epiglottidean folds, which folds are the lateral boundaries of the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms by its reduplication the chief part of the superior or false vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The forepart of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryteno-epiglottidean folds, and the true vocal cords are covered by stratified squamous epithelium; the rest of the laryngeal mucous membrane is covered by columnar ciliated cells.

The mucous membrane above the rima glottidis is extremely sensitive, and during life the lightest touch of a foreign body produces cough.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the
arytenoid glands. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the surface of the true vocal cords.

Vessels and Nerves.—The arteries of the larynx (Fig. 977) are the laryngeal branches derived from the superior and inferior thyroid. The superior laryngeal artery from the superior thyroid courses along by the internal laryngeal nerve; the inferior laryngeal artery from the inferior thyroid courses along with the recurrent laryngeal nerve. The veins accompany the arteries; those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The laryngeal lymphatics arise from a network in the mucous membrane. This network is divisible into two portions, a superior and an inferior, which are to be regarded as almost independent areas. The superior region includes all of the "laryngeal mucous membrane above the glottis, epiglottis, aryteno-epiglottidean folds, interarytenoid region, and superior vocal cords." The inferior area is the laryngeal mucous membrane below the glottis. The lymphatics of one-half of the larynx do not communicate with those of the other half in the median line in front, but do in the median line behind. The efferent vessels from the superior network accompany the superior laryngeal artery, pierce the thyro-hyoid membrane, and divide into three sets. One or two lymphatic vessels pass upward and terminate in a gland slightly below the posterior belly of the Digastric muscle. A group of vessels passes horizontally outward to terminate in the glands situated on the internal jugular vein on a level with the bifurcation of the common carotid artery. Another group descends and empties into the internal jugular group of glands at a lower level than the horizontal vessels. Trunks from the inferior network of the laryngeal mucous membrane form two groups. The anterior or supracricoid group consists of three trunks which pass through the cricothyroid membrane, to empty into the pre-laryngeal glands, the pre-tracheal gland, and the middle and lower deep cervical glands. The posterior group consists

1 Philip R. W. De Santi in the Lancet, June 18, 1904.
2 Poirier, Cunéo, Most, De Santi.
of "from three to five trunks, which pass over the crico-tracheal fascia at the junction of the lateral and posterior aspects of the trachea," and terminate in the recurrent glands about the recurrent laryngeal nerve. The nerves are derived from the internal and external laryngeal branches of the superior laryngeal nerve, from the inferior or recurrent laryngeal, and from the sympathetic. The internal laryngeal nerve is almost entirely sensory, but some motor filaments are said to be carried by it to the Arytenoideus muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryteno-epiglottidean folds, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal nerve supplies the Crico-thyroid muscle. The recurrent laryngeal passes upward under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Crico-thyroid and part of the Arytenoideus. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibres ascend to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryteno-epiglottidean folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

THE TRACHEA AND BRONCHI (Fig. 978).

The trachea or windpipe is a cartilaginous membranous, elastic, cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the body of the fourth, or sometimes of the fifth, dorsal vertebra, where it divides (bifurcatio tracheae) into two bronchi, one for each lung. This point is at the level of the spine of the fourth dorsal vertebra. The trachea is found to be more deeply placed the lower down it is examined. It is in the median line, deviating below a very little to the right side. When a cross-section is made of the trachea it is seen that its anterior and lateral walls are rounded, but its posterior wall is flat (Fig. 982). The largest diameter of the tube is the middle; from this point the diameter diminishes toward the bronchi and toward the laryngeal end. The trachea measures about four inches and a half in length; its diameter from side to side is from three-quarters of an inch to an inch, being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroidea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and more superficially, by the anastomosing branches between the anterior jugular veins: in the thorax it is covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the oesophagus; laterally, in the neck, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, in the thorax, it lies in the upper part of the interpleural space, that is, in the superior mediastinum, and is in relation on the right to the pleura and right vagus, and near the root of the neck to the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, the left common carotid and subclavian arteries.

The Right Bronchus (bronchus dexter).—The unbranched portion of the right bronchus, wider, shorter, and more vertical in direction than the left, is about an inch in length, and enters the hilum of the right lung opposite the fifth dorsal
THE TRACHEA AND BRONCHI

1377

vertebra. It forms an angle to the median plane of about 29 degrees. The vena azygos major arches over it from behind; and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the eparterial branch (*ramus bronchialis eparterialis*), because it is given off above the right pulmonary artery. The bronchus now passes below the artery, and is

![Diagram of larynx, trachea, and bronchi](image)

**Fig. 978.—Front view of cartilages of larynx; the trachea and bronchi (the right bronchus is not shown as steep as it really is).**

known as the hyparterial branch (*ramus bronchialis hyparterialis*). It divides into two branches for the middle and lower lobs.

If a transverse section of the trachea is made a short distance above its point of bifurcation, and a bird’s-eye view taken of its interior (Fig. 982), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact
serves to explain why a foreign body in the trachea more frequently falls into the right bronchus than into the left.\footnote{Reigel asserts that the entrance of a foreign body into the left bronchus is by no means so infrequent as is generally supposed. See also Med.-Chir. Transactions, vol. lxxi. p. 121.—Ed. of 15th English edition.}

The Left Bronchus (bronchus sinister).—The left bronchus is smaller and longer than the right, being nearly two inches in length. It forms an angle to the median plane of about 46 degrees. It is slightly curved and enters the root of the left lung, opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the oesophagus, the thoracic duct, and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. The left bronchus has no branch corresponding to the eparterial branch of the right bronchus, and therefore it has been supposed by some that there is no upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung. The left bronchus does have an hyparterial branch.

When the main or stem bronchus enters the lung on each side it appears to divide into nearly equal branches at the root of the lung, but a somewhat similar arrangement to what is found in many animals may be made out where each main bronchus passes downward and backward toward the extremity of the lower lobe, and ends near the posterior surface of the base of the lung, a portion of pulmonary substance which is between the Diaphragm and the wall of the chest. It gives off four branches, or lateral bronchi (rami bronchiales), at intervals in two directions, dorsally and ventrally, and, in addition, accessory branches, which arise from the front of the bronchus and pass mesially and dorsally into the inferior lobe. In the right bronchus the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first central branch supplies the superior lobe, and all the others, both ventral and dorsal, go to the lower lobe. The dorsal and ventral branches divide into smaller branches, and these again into smaller branches or bronchioles (Fig. 981). Each bronchiolus divides into minute branches (bronchioli respiratorii) (Fig. 981), the walls of which show numerous areas of bulging called alveoli (Fig. 981). From the bronchioli respiratorii come the terminal branches of the bronchi. These terminal branches are the alveolar ducts (ductuli alveolares), and they are bulged by numerous alveoli (Fig. 981). They connect by openings at their termination with several cavities of irregular form, which are called atria. Each atrium is connected with several or many larger cavities, known as sacculi alveolares, air-cells, or air-sacs (infundibula). The entire surface of the air-sacs is filled with small cavities, the pulmonary alveoli (alveoli pulmonis). An alveolar duct with its branches forms a pulmonary lobule (lobulus pulmonis) (Fig. 980).

Structure of the Trachea.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

The Cartilages.—The cartilages vary from sixteen to twenty in number; each forms an imperfect ring, which surrounds about two-thirds of the cylinder of the
trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth, and half a line in thickness. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The First Cartilage is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The Last Cartilage is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, embedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The Muscular Fibres.—The muscular fibres are disposed in two layers, longitudinal and transverse.
THE ORGANS OF VOICE AND RESPIRATION

The Longitudinal Fibres are the most external, and consist merely of a few scattered longitudinal bundles of fibres.

The Transverse Fibres constitute the Trachealis muscle of Todd and Bowman. The most internal form a thin layer which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

The Mucous Membrane.—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting a layer of columnar, ciliated epithelium, between the deeper ends of which are smaller triangular cells, the bases of which, often branched, are attached to the basement-membrane. These triangular cells are mucus-secreting, and may be seen as goblet-cells or chalice-cells when their contents have been discharged. In the deepest part of the mucous membrane, and especially between the mucous and submucous layers, longitudinally arranged fibres are very abundant and form a distinct layer.

The Tracheal Glands (glandulae tracheales).—The tracheal glands are found in great abundance at the posterior part of the trachea. They are racemose glands, and consist of a basement-membrane lined by columnar mucus-secreting cells. They are situated at the back of the trachea, outside the layer of muscular tissue, between it and the outer fibrous layer. Their excretory ducts pierce the muscular and inner fibrous layers, and pass through the submucous and mucous layers to open on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The veins terminate in the thyroid venous plexus. The nerves are derived from the pneumogastric and its recurrent branches and from the sympathetic.

Lymphatic Glands.—The trachea is surrounded by lax connective tissue which contains numerous lymph glands, known as the peritracheo-bronchial glands. They are divided into four groups (Baréty). A group to the right side, in the angle between the trachea and right bronchus and ascending to the region of the subclavian vessels. A group to the left side, in the angle formed by the trachea and left bronchus, and ascending to about the arch of the aorta and the recurrent laryngeal nerve. The two groups just described are usually called tracheal glands (lymphoglandulae tracheales). A third group is in the angle formed by the bifurcation of the trachea. These constitute the bronchial glands (lymphoglandulae bronchiales). They number ten or twelve (Cunéo). A fourth group, the interbronchial glands, are found in angles of bifurcation of the larger bronchi in the lung parenchyma. Very early in life the peritracheo-bronchial glands become dark or even black from the deposition of carbonaceous substance brought by the leukocytes from the bronchial tubes. This condition is called anthracosis.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can readily be distinguished. In the receding angle below the chin the hyoid bone can easily be made out, and a finger’s breadth below it is the pomeum Adami, the prominence between the upper borders of the two alae of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.
With the laryngoscope, the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx, bounded on either side by the aryteno-epiglottidean folds, in which may be seen two rounded eminences corresponding to the cornicula and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—Foreign bodies often find their way into the air-passages. These may be either large soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during inspiratory efforts, and produce attacks of dyspnea from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which, as stated above, more often is the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "adenoma of the glottis." This effusion does not extend below the level of the true vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as "clergyman's sore throat." It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which incites increased activity in the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculosis disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened surgically in two different situations: through the crico-thyroid membrane (laryngotomy), or in some part of the trachea (tracheotomy); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cartilage with the upper ring of the trachea (laryngo-tracheotomy).

Laryngotomy is anatomically the more simple operation: it can readily be performed, and should be employed in those cases where the air-passages require opening in an emergency for the relief of some sudden obstruction to respiration. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross-cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy tube is introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut, through both the superficial and deep structures, and thus to open at once the air-passages. It will be seen, however, that in opening in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.
Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and enclose the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally, also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroid ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphé divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea is cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision to expose it must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in others.

A portion of the larynx or the whole of it has been removed or malignant disease, laryngoectomy.

Some surgeons do preliminary tracheotomy, insert a Trendelenburg cannula to prevent the flow of blood downward into the lungs, and then remove the larynx. Other surgeons do not employ preliminary tracheotomy.

Perier’s method of laryngoectomy is as follows: Make a vertical incision in the median line from the level of the hyoid bone to below the level of the cricoid cartilage. Make a transverse incision at each end of the vertical incision. This makes an I-shaped wound. Separate the soft parts from the larynx and upper part of the trachea, and separate these two structures from the oesophagus. After arresting bleeding, divide the trachea below the cricoid cartilage, introduce a special cannula, complete the removal of the larynx, suture the opening of the trachea to the lower angle of the wound, and close the rest of the wound after securing drainage. In malignant disease of the larynx the associated lymphatic glands must be removed.

Partial laryngoectomy, according to Sir F. Semon, is the removal of not less than one wing of the thyroid cartilage. Removal of a lesser piece of the thyroid or of a bit of the arytenoid or cricoid he considers with the operation of thyrotomy.

THE PLEURAE (Figs. 983, 984, 985, 986, 987).

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the pleura, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes is called the pulmonary pleura or the visceral layer of the pleura (pleura pulmonalis) (Fig. 983), while that which lines the inner surface of the chest is called the parietal layer of the pleura (pleura parietalis) (Fig. 983). The two layers join at the hilum of the lung. The space between these two layers is called the cavity of the
pleura (cavum pleurae), and contains a very little clear fluid. It must be borne in mind that in the healthy condition the two layers are in contact, and there is no real cavity until the lung becomes collapsed and separates from the wall of the chest. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate from each other.

The two pleurae do not meet in the middle line of the chest, excepting anteriorly opposite the second and third pieces of the sternum—a space being left between
them, which contains all the viscera of the thorax excepting the lungs; this is the mediastinum.

Reflections of the Pleurae (Fig. 983). The Pleura Pulmonalis (Fig. 983).—The pleura pulmonalis is closely attached to the surface of the lung and enters the depths of the interlobar fissures. It leaves the lung surface at the hilum, covers the root of the lung for a little way (Figs. 990 and 991), and then passes into the mediastinum.

Reflections of the Pleurae (Fig. 983). The Pleura Pulmonalis (Fig. 983).—The pleura pulmonalis is closely attached to the surface of the lung and enters into the mediastinum.
The Pleural Membrane.—Between the hilum and the mediastinal pleura there is a thickened pleural fold, triangular in outline, and called the ligamentum pulmonale or the ligamentum latum pulmonis (Figs. 990 and 991). It is formed by the two layers of the pulmonary pleura coming in contact below the root of the lung. This fold passes from the lower part of the inner pulmonary surface to the pericardium, and the lower border is free or attached to the diaphragmatic pleura. In the right lung the origin of this ligament is in front of the groove for the azygos vein; in the left lung it is in front of the groove for the thoracic aorta.

The Pleura Parietalis.—The pleura parietalis is a continuous membrane, but for convenience is divided into the cervical pleura, costal pleura, mediastinal pleura, and diaphragmatic pleura.

The Cervical Pleura or Dome of the Pleura or Cupola (cupula pleurae) (Fig. 986) is the dome-shaped roof of the cavity of the pleura. It projects above the apex of the lung to the neck of the first rib. As the first rib is placed obliquely, the dome of the pleura reaches from one inch to two inches above the anterior extremity of the first rib, and from one-half an inch to one and one-half inches above the clavicle. On the outer side of the cervical pleura are the Scalenus anterior and medius muscles. Just below the apex, on the anterior and inner surface, is a groove for the subclavian artery, which vessel passes over it in an arch (Fig. 984). A little below the groove for the subclavian artery is a broader and shallower groove for the innominate and subclavian veins. Above the subclavian artery and in front above the cervical pleura are the cords of origin of the brachial plexus and the inferior cervical ganglion (Fig. 984). The dome is strengthened and kept in place by Sibson's aponeurosis or the vertebro-pleural ligament (Figs. 985 and 986). This comes from a little piece of muscle, the Scalenus minimus muscle, which originates from the transverse process of the seventh cervical vertebra, broadens and becomes aponeurotic as it descends, and is inserted into the inner margin of the first rib (Figs. 984 and 985). It is also strengthened by the costa-pleural ligament (Fig. 985), from the inner surface of the neck of the first rib to the pleura, and by fibrous bands which pass to the tissue about the subclavian sheath, trachea, and oesophagus (Fig. 985).

The Costal Pleura (pleura costalis) (Fig. 983) is the shortest portion of the pleura and is connected to the parts it covers by the endothoracic fascia (fascia endothoracica), a layer of connective tissue which is much thicker back of the rib cartilages than it is posteriorly. The costal pleura covers the inner surface of part of the sternum, the costal cartilages, ribs, and Intercostal muscles, and the sides of the bodies of the dorsal vertebrae. This layer is loosely attached except as it passes from the heads of the ribs to the vertebrae, where it is firmly adherent.

The Mediastinal Pleura (pleura mediastinalis) (Fig. 985) covers the septum of the mediastinum, which intervenes between the two pleural cavities. The mediastinal pleura extends from the inner surface of the anterior wall of the thorax to the vertebral column. It is continuous in front and back with the costal pleura of the same side, the lines of junction being known, respectively, as the anterior line of pleural reflection and the posterior line of pleural reflection. Below the mediastinal pleura passes into the diaphragmatic pleura of the same side. The portion of the mediastinal pleura which fuses with the parietal layer of the pericardium is called the pericardial pleura (pleura pericardiae).

Above the root of the lung the mediastinal pleura passes back directly to the vertebral column. "In this region the left mediastinal pleura is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein, and the left common carotid, and left subclavian arteries; to the oesophagus and the thoracic duct. The right mediastinal pleura, on the other hand, is applied, above the level of the root of the lung, to the upper part of the vena cava and right innominate vein; to the right innominate artery; to the vena azygos major, as it hooks forward above the bronchus; to the vagus and phrenic
nerves; and to the right side of the trachea."

Upon the pericardium the phrenic nerve is covered by the pleura. Back of the root of the lung and the pulmonary ligament, the right mediastinal pleura passes back to the vertebrae to the left of the oesophagus; the left mediastinal pleura passes back over the descending aorta, and just above the Diaphragm and in front of the aorta over the lower end of the oesophagus.

The Diaphragmatic Pleura (pleura diaphragmatica) (Figs. 987 and 988) covers the upper surface of the Diaphragm outside of the base of the pericardium, but does not completely cover it; for it does not pass into the interval between the wall of the thorax and Diaphragm, and before this point is reached becomes continuous with the costal pleura.

The reflection to the costal pleura begins by the sternum, at the lower margin of the sixth rib; takes place at the junction of the cartilage of the rib with the seventh rib; posteriorly, it takes place at the lower margin of the twelfth dorsal vertebra.

In the front of the chest, where the parietal layer of the pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a considerable extent. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sterno-clavicular articulation to the mid-point of the junction of the manubrium to the body of the sternum. From this point the two pleurae descend in close contact to the level of the fourth costal cartilages. Here the line of reflection on the right side is continued downward in nearly a straight line to the lower end of the gladiolus and then turns outward behind the costal cartilage of the sixth rib; takes place at the junction of the cartilage of the rib with the seventh rib; and from here the reflection diverges outward, so that opposite the seventh cartilage it is about three-quarters of an inch from the left border of the sternum. It, however, always extends considerably farther over the pericardium than the corresponding lung. From this joint the reflections of the two sides are practically the same. The lower limit of the pleura is on a considerably lower level than the lower limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the internal intercostal muscles. In ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of pleural reflection, with the result that the costal and diaphragmatic pleura are here in contact, the narrow slit between the two being termed the phrenico-costal sinus (sinus phrenicocostalis) (Fig. 987). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the costo-mediastinal sinus (sinus costomediastinalis).

Along the line of reflection of the diaphragmatic pleura a dense fascia passes from the costal cartilages and the uncovered portion of the Diaphragm to the costal pleura. This serves to hold it in place. It is named by Cunningham the phrenico-pleural fascia.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm; throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

1 Cunningham's Text-book of Anatomy.
The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

**Structure of the Pleura.**—The pleura is composed of connective tissue containing much elastic tissue, its free surface being covered with flat endothelial cells. It is fastened to adjacent structures by subserous areolar tissue. The subserous tissue of the visceral pleura is continuous with the areolar tissue of the lung.

**Vessels and Nerves.**—The arteries of the pleura are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiac, and bronchial. The veins correspond to the arteries. The lymphatics are very numerous in the pleura and subserous tissue. Many of them are in direct communication with the pleural cavity by stomata between the endothelial cells. Stomata are absent in the mediastinal pleura and over the ribs (Dyskowsky). The lymphatics of the visceral layer empty into the superficial pulmonary trunks; the lymphatics of the costal pleura empty into the intercostal trunks; of the diaphragmatic pleura, into the diaphragmatic trunks; of the mediastinal pleura, into the posterior mediastinal glands. The nerves are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleural pulmonalis.

**Surgical Anatomy.**—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed, in order to give more room. It is best to keep the incision at least one inch below the last rib, enlarging the wound afterward, when the finger can be introduced as a guide.

In wounds of the Diaphragm the pleura may be injured. In operations about the root of the neck, especially in the removal of glands and the ligation of the first part of the subclavian artery, the pleura may be injured.

Punctured wounds of the root of the neck are apt to reach the pleura. Emphysema is a surgical disease. In acute emphysema the treatment is drainage. A portion of the fifth or sixth rib in the axillary line is removed by subperiosteal resection, the pleura is opened, and a tube is introduced. In chronic emphysema the lung is contracted and adherent and cannot expand; hence drainage will not cure it. It is necessary to perform multiple rib resection in order to permit the chest-watt to sink in and obliterate the cavity, which, as the lung is unable to expand, it cannot do. The necessary operation may be the operation of Estlander, or the operation of Schiede, or the operation of Fowler (page 166).

If a large wound admits suddenly a quantity of air into the pleura, dangerous or fatal pneumothorax arises, and the lung collapses. This is best met during operations by using the Fell-O'Dwyer apparatus for artificial respiration as advised by Matas. This apparatus keeps the lung expanded, in spite of the entrance of air into the pleural sac. In surgical pneumothorax the lung may be sutured to the chest-wall, so as to block the opening. Sometimes, in order to arrest dangerous pulmonary bleeding, a surgeon deliberately induces pneumothorax, in hope that the collapse of the lung will arrest bleeding.

When an abscess of the liver is posterior and on the dorsum, transpleural hepateotomy is performed. A portion of the tenth and eleventh ribs below the angle of the scapula is removed. As a rule, the pleura is found obliterated at this point. If it is opened, it is at once sutured or closed with gauze packing. The exposed Diaphragm is incised, and, as it is usually adherent to the liver, the abscess cavity is entered. If it is not adherent, the liver is exposed and the abscess sought for with an aspirating-needle.

**THE MEDIASTINAL SPACE, INTERPLEURAL SPACE OR MEDIASTINUM.**

The mediastinum is the space left in the median portion of the chest by the non-approximation of the two pleure. It extends from the sternum in front to the spine behind. Within it are the contents of the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an upper portion, above the upper level of the pericardium, which is named the

1 Poirier, Cunéo, and Delamare on the Lymphatics. Translated and edited by Cecil H. Leaf.
2 Annals of Surgery, April, 1899.
superior mediastinum (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the middle mediastinum; that part which is in front of the pericardium, the anterior mediastinum; and that part which is behind the pericardium, the posterior mediastinum.

Fig. 988.—The posterior mediastinum.

The Superior Mediastinum (Fig. 989).—The superior mediastinum is that portion of the interpleural space which lies above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebrae behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra,
and laterally by the lungs and pleurae. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longus colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, oesophagus, and thoracic duct; the remains of the thymus gland and some lymphatic glands.

The Anterior Mediastinum (Fig. 983).—The anterior mediastinum is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above obliquely downward and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three lymphatic glands (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

The Middle Mediastinum (Fig. 983).—The middle mediastinum is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The Posterior Mediastinum (Figs. 983 and 987).—The posterior mediastinum is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the oesophagus, thoracic duct, and some lymphatic glands.
Blood-vessels.—The areolar tissue of the anterior mediastinum receives numerous mediastinal branches from the internal mammary artery. The areolar tissue of the posterior mediastinum receives mediastinal branches from the descending thoracic aorta. The lowest mediastinal vessels lie upon the Diaphragm and are called superior phrenic arteries. The vena cava and internal mammary veins receive mediastinal branches.

The anterior mediastinal lymphatic glands are in the upper portion of the anterior mediastinum. They are five or six in number and are placed in front of the transverse arch of the aorta. Chains of glands run up from them to the root of the neck. On the right side they are around the left common carotid and left subclavian arteries.

The posterior mediastinal glands are around the oesophagus, particularly in front of it. The peritracheo-bronchial glands have been described.

THE LUNGS (PULMONES) (Figs. 983, 990, 991, 992, 993, 994, 995).

The lungs are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. A healthy lung hangs free within the pleural cavity. It is suspended by the root and by the ligamentum pulmonis. In many cases examined the lung does not hang free, but, as a result of former pleurisy, an area of the pulmonary pleura is adherent to the parietal pleura. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces.

The Apex (apex pulmonis).—The apex forms a tapering cone which extends into the root of the neck about an inch to two inches above the level of the anterior

---

1 Poirier, Cunéo, and Delamare on the Lymphatics. Translated and edited by Cecil H. Leaf.
extremity of the first rib. The brachial plexus is in close proximity to this portion of the lung.

The Base (basis pulmonis).—The base is broad, concave, and rests, by its diaphragmatic surface (facies diaphragmatica), upon the convex surface of the Diaphragm, which separates the right lung from the upper surface of the right lobe of the liver and the left lung from the upper surface of the left lobe of the liver, the fundus of the stomach, and spleen; its circumference is thin, and projects for some distance into the phrenico-costal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

Surfaces. The External, Costal or Thoracic Surface (facies costalis) (Figs. 994 and 995).—The external, costal, or thoracic surface is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front. In a hardened specimen this surface has grooves and bulgings on it, corresponding to the ribs and intercostal spaces.

The Inner or Mediastinal Surface (facies mediastinalis) (Figs. 990 and 991).—The inner or mediastinal surface is concave. It presents in front a depression corresponding to the convex surface of the pericardium, and behind a deep fissure, the hilum (hilus pulmonalis). In the hilum lie the bronchi, vessels, nerves, and lymph-nodes, which together constitute the root of the lung. On the inner and anterior surface, a little below the apex, is a groove, the subclavian groove (sulcus subclavii), for the subclavian artery. A little lower is a broader and shallower groove for the innominate and subclavian veins. The pleura lies between the lungs and these vessels. In front of the hilum and below it is a depression for the heart (impressio cardiaca). It is deeper on the left than on the right side. On the right side it passes into the groove from the superior vena cava and the vena azygos major. On the left side, behind the hilum, is a groove for the thoracic aorta; on the right side a groove for the oesophagus.
Borders. The Inferior Border \textit{(margo inferior).—} The inferior border is the line of junction of the costal and diaphragmatic surfaces. Posteriorly, it is rounded and broad, and is received into the deep concavity on either side of the spinal column (Fig. 996). It is much longer than the anterior border, and projects, below, into the phrenico-costal sinus.

![Image of the heart and lungs]

**Fig. 992.—** Front view of the heart and lungs.

The Anterior Border \textit{(margo anterior).—} The anterior border is thin and sharp, overlaps the front of the pericardium, and is projected into the costo-mediastinal sinus of the pleura. The anterior border of the right lung is almost vertical; that of the left presents, below, an angular notch, the \textit{incisura cardiaca}, into which the heart and pericardium are received. A projection from the upper lobe comes forward beneath the cardiac notch; it is called the \textit{lingula pulmonis}.

The Lobes of the Lungs (Figs. 994 and 995).—Each lung is divided into two lobes, an \textit{upper (lobus superior)} and a \textit{lower (lobus inferior)}, by a long and deep fissure (\textit{incisura interlobaris}), which extends from the upper part of the posterior border of the organ about three inches from its apex, downward and forward to the lowest part of the lung just external to its anterior border. This fissure penetrates nearly to the root. The upper lobe is the smaller; the lower lobe is the larger. In the right lung the upper lobe is partially subdivided by a second and shorter fissure, which extends almost horizontally forward from the middle of the preceding to the anterior margin of the organ, marking off a small triangular portion, the \textit{middle lobe (lobus medius)}.

The right lung is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in
consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The Root of the Lung (radix pulmonis) (Figs. 990, 991, 992, and 993).—A little above the middle of the inner surface of each lung, and nearer its posterior
than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta, and below the vena cava and trachea. The root of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz., the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus: On the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. It should be noted that the entire right bronchus does not lie above the right pulmonary artery, but only its eparterial branch (see p. 1377), which passes to the upper lobe of the right lung; the divisions of the bronchus for the middle and lower lobes lie below the artery.

The true weight of the human lungs as ascertained in the bodies of criminals executed by electricity, in which the mode of death is attended by a nearly bloodless condition of the lungs, is 215 grams (7½ ounces) for the left lung and 240 grams (8½ ounces) for the right lung (E. A. Spitzka, Amer. Jour. of Anat., iii., 1, p. v.). Ordinarily, with the vascular channels more or less filled with blood and serum, the two lungs together weigh about 42 ounces, the right lung being 2 ounces heavier than the left, but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female. The specific gravity of the lung-tissue varies from 0.345 to 0.746.

The color of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior surface of the lung is usually darker than the anterior.

The surface of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The substance of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

The Fetal Lung.—After respiration has been established, the lung fills the pleural cavity. In the fetus, as the lung has never been distended with air and has never received a large amount of blood, it is gathered into a small mass at the back of the thorax. It will sink in water and feels solid to the touch.

Structure.—The structure of the lung is such that the blood brought by the pulmonary artery comes into close relation with the air which enters from the bronchioles. The blood gives materials to the air, and the air gives elements to the blood, and the process of respiration causes the dark blood brought from the heart by the pulmonary artery to return to the heart as red blood in the pulmonary vein. The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The Serous Coat.—The serous coat is thin, transparent, and invests the entire organ as far as the root. It is known as the pulmonary pleura (p. 1384).
The Subserous Areolar Tissue.—The subserous areolar tissue contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules, and at the hilum forms the pulmonary scaffold or framework.

The Parenchyma.—The parenchyma is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the foetus. The lobules vary in size; those on the surface are large, of pyramidial form, with the bases turned toward the surface; those in the interior are smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

The Bronchus (pp. 1377 and 1378) (Figs. 980, 981, and 982).—The bronchus, upon entering the substance of the lung, divides and subdivides bipinnately, throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobule, and is termed a lobular bronchial tube or bronchiole (bronchioli). Each bronchiole divides into minute branches (bronchioli respiratorii), the walls of which now begin to present irregular dilatations, bronchial alveoli. These are present at first sparsely and on one side of the tube only, but as it proceeds onward these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character. The terminal branches come from the bronchioli respiratorii. These terminal branches are called the alveolar ducts or alveolar passages (ductuli alveolares). The alveolar ducts show numerous alveoli (Fig. 981) and join with cavities called atri. Each atrium joins several larger cavities, the air-cells or air-sacs (infundibula). The numerous small cavities on the surface of the air-sacs are the pulmonary alveoli (alveoli pulmonis). The bronchiole now becomes widened out and terminates in an irregular cul-de-sac, the air cell, air sac alveolus or infundibulum. The walls of the infundibulum are closely beset in all directions by pulmonary alveoli or pulmonary air cells. Professor Gerrish remarks that the first of the alveoli seen on the bronchioles before the coreal ends are formed would seem an effort on the part of nature to form an infundibulum before all the necessary conditions are favorable.

Changes in the Structure of the Bronchi in the Lungs.—Within the lungs the bronchial tubes are circular, not flattened (Fig. 982), and present certain peculiarities of structure.

In the Lobes of the Lungs.—In the lobes of the lungs the following changes take place: The cartilages are not imperfect rings, but consist of thin laminae, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes, the diameter of each of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The fibrous coat is continued into the smallest ramifications of the bronchi. The muscular coat is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The mucous membrane lines the bronchi and their ramifications throughout, and is covered with columnar ciliated epithelium.

In the Lobules of the Lung.—In the lobular bronchial tubes and in the infundibula the following changes take place: The muscular tissue begins to disappear, so that in the infundibula there is scarcely a trace of it. The fibrous coat becomes thinner, and degenerates into areolar tissue. The epithelium becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchioles
patches of non-ciliated flattened epithelium may be found scattered among the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs, in clusters of two or three, between the others.

The air-cells are small, polyhedral recesses composed of a fibrillated connective tissue and surrounded by a few involuntary muscular and elastic fibres. Free in their cavity are to be seen under the microscope granular, rounded, ameoboid cells (eosinophile leukocytes), often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{10}$ to $\frac{1}{10}$ of an inch in diameter, being largest on the surface at the thin borders and at the apex, and smallest in the interior.

**Mucous Glands.**—In the larger bronchi the mucous membrane contains goblet cells. When the tubes diminish to 1 mm. in diameter the glands grow fewer. In the smaller bronchi there are no mucous glands.

**Vessels of the Lungs.**—The **pulmonary artery** (Figs. 992 and 993) conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network upon the walls of the intercellular passages and air-cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The **pulmonary capillaries** form plexuses which lie immediately beneath the mucous membrane in the walls and septa of the air-cells and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin. The arteries of neighboring lobules are independent of each other, but the veins freely anastomose together.

The **pulmonary veins** commence in the pulmonary capillaries, the radicles coalescing into larger branches, which run along through the substance of the lung, independently from the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the organ. Finally they open into the left auricle of the heart, conveying oxygenated blood to be eventually distributed to all parts of the body by the aorta.

The **bronchial arteries** supply blood for the nutrition of the lung. The thoracic aorta usually gives off two left bronchial arteries. The single right bronchial artery usually arises from the first right aortic intercostal, but sometimes from the superior left bronchial artery, or from the aorta. In the root of the lung they are posterior to the bronchi, they accompany the bronchial tubes, supply the tubes and pulmonary tissue, and give branches to the walls of the larger pulmonary vessels, the oesophagus, pericardium, and bronchial glands. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network. There may be but one bronchial artery; there may be three or four.

The **bronchial veins** are not found in the walls of the very small bronchi. The small bronchial veins run along the front and back of the median sized and

---

1 The meshes are only 0.002" to 0.008" in width, while the vessels are 0.003" to 0.005" (Köllicher, Human Microscopic Anatomy).—Ed. of 15th English edition.
larger tubes, and from two trunks at the root of each lung. These vessels terminate on the right side in the vena azygos major, and on the left side in the superior intercostal or left upper azygos vein. Tracheal and posterior mediastinal veins open into the bronchial veins. The venous blood from the smaller tubes passes to the pulmonary veins.

The lymphatics begin in networks about the lobules and form networks about the bronchi and beneath the bronchial mucous membrane. The superficial collecting trunks arise about the lobules and beneath the pleura. According to Sappey, the superficial trunks from the upper lobe begin on the costal surface; one set passes around the anterior border, another set around the posterior border, and a third into the incisura interlobaris. The same observer says that the superficial trunks from the middle lobe unites with the trunks from the upper and lower lobes; and the superficial trunks from the lower lobe, like those of the upper lobe, are in three sets. One set passes around the posterior margin, one around the anterior margin, and one into the incisura interlobaris. All of the superficial trunks convey lymph to the glands of the hilum. Some of the deep collecting trunks begin by the sides of the small bronchi; others course along by the pulmonary veins or pulmonary arteries. All of them pass to the glands of the hilum. The glands of the hilum are in communication with the peritracheo-bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, and are lost upon them. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sermo-mastoid muscle. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sermo-mastoid muscle, downward and inward across the sternoclavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura extends farther down than the lung, so that it may be wounded, and a wound may pass through its cavity into the Diaphragm, and the abdominal viscera may be injured without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outward.

"The position of the great fissure of the lungs may be indicated by a line drawn from the third
dorsal spine obliquely downward in such a manner as to reach the sixth rib close to the midclavicular line. The interlobar fissure between the upper and middle lobes of the right lung corresponds to a line drawn from the apex of the axilla almost horizontally to the sternum, reaching the latter at about the level of the fourth costal cartilage" (Erendrath).

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.
The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—i.e., the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem to be a most unusual injury, and the exact mode of its causation is difficult to understand. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, the lung is not able to recede, and consequently gives way.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and the pleura pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the parieties of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air may pass straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes, therefore, an important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety; that is to say, from external wounds, from stabs and gunshot injuries, in which cases air passes either from the wound of the lung or from an external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parieties of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes a so-called hernia of the lung. True hernia of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls during inspiration, and disappears on holding the breath. Wounds of the lung may produce dangerous or fatal hemorrhage into the pleural sac. In many cases the bleeding is spontaneously arrested; in others the surgeon must interfere to save life. In some cases air has been admitted by intercostal incision and the insertion of a tube, and pulmonary collapse has arrested bleeding. In other cases it is necessary to resect portions of several ribs, and stop bleeding by ligatures or suture ligatures. In one case of a furious secondary hemorrhage following a gunshot wound, the editor resected several ribs, packed the pleural cavity about the lung with sterile gauze, to obtain a base of support, and then arrested the bleeding by packing iodoform gauze against the firmly supported lung. This patient recovered.

Incision of the lung (pneumotomy) is performed for pulmonary abscess (either tuberculous or pyogenic), pulmonary gangrene, hydatid cysts, and bronchiectasis. In pulmonary abscess, locate the area by physical signs and the x-ray, resect a portion of a rib over it, and note if the pleura is adherent. If it is adherent, continue the operation. If it is not adherent, insert stitches of catgut through the two layers of pleura and the superficial part of the lung, so as to encircle a considerable area, and then wait several days for adhesions to form. Adhesions protect the pleura from infection, and, by keeping air from the pleural sac, prevent pneumothorax. When ready to continue the operation, locate the abscess with an aspirating-needle and syringe, open it with a cautery at a dull-red heat, and drain by means of a tube.

Pneumotomy is very unsatisfactory in tuberculous cavities and bronchiectasis. In tuberculosis, excision of the diseased area (pneumoneotomy) has been employed, but it is not to be advised.
THE DUCTLESS GLANDS.

THESE glands do not possess excretory ducts. They furnish materials which are added to the blood or lymph as it passes through them. The material from each gland is known as an internal secretion. Some of these secretions are powerful materials and influence profoundly the body nutrition. The ductless glands are usually given as follows: the spleen, the lymphatic glands, the pineal gland, the pituitary body, the suprarenal capsules, the thyroid gland, the para-thyroids, the thymus, the carotid body, and the coccycgeal body. The lymphatic glands were described in a special section (p. 772). The lymphatic glands are not considered to be really glands, but, nevertheless, as lymph passes through the lymph glands, it receives a product of the glands, namely, lymphocytes. There is no evidence that the spleen furnishes an active internal secretion, and this organ has been studied with the abdominal viscera. The pineal gland (p. 905) and pituitary body (p. 882) were considered with the brain. The suprarenal capsules (p. 1428) are described with the kidneys. Some glands, for instance, the liver, pancreas and testicle, have an external secretion and also an internal secretion.

THE THYROID BODY OR GLAND (GLANDULA THYREOIDEA)  
(Fig. 997).

The thyroid gland is an extremely vascular body, situated at the front and sides of the neck, and extending upward upon each side of the larynx. It is a single gland, varying greatly in size in different individuals. It is larger relatively in females and in children than in men. It is frequently asymmetrical. In early embryonal life the gland has a duct, the thyro-glossal duct (ductus thyreoglossus), which passes from the isthmus of the thyroid to the foramen caecum of the dorsum of the tongue. The lumen of this duct is obliterated early and becomes a cord of epithelium. The lower portion of the duct often remains open for a little way. The upper portion remains as the foramen caecum. The situation of this obliterated fetal duct may be marked by the third or middle lobe of the thyroid gland. The thyroid surrounds the upper portion of the trachea like a horseshoe. It consists of two lateral lobes connected across the middle line by a narrow transverse portion, the isthmus.

The weight of the gland is somewhat variable, but is usually about one ounce. It is somewhat heavier in the female, in whom it becomes enlarged during menstruation and pregnancy. As age advances the weight of the thyroid diminishes.

The color of the thyroid, as seen from the surface, is reddish-blue. The gland is surrounded by a closely adherent thin connective-tissue capsule of the pre-tracheal layer of deep cervical fascia. From the inner surface of the capsule come delicate septa, which enter into the thyroid body and separate it into lobes and also separate the lobes into lobules. The blood-vessels lie beneath the capsule. The anterior and lateral portions of the gland are covered by the capsule. "Passing around the side of the gland to its posterior surface, this capsule then splits into two portions. One remains in contact with the gland and invests its posterior surface. The other, the thicker of the two, passes to the posterior surface of the pharynx.
and oesophagus, thus enclosing them with the larynx, trachea, and thyroid gland, in a common sheath.\textsuperscript{1}

The \textit{lateral lobes} are conical in shape, the apex of each being directed upward and outward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring. The summit of the lateral lobe not unusually is pointed and reaches to the level of the oblique line upon the ala of the thyroid cartilage or even higher. The right is, as a rule, somewhat larger than the left lobe. The lower portion of the gland, when the head is extended, is about one inch above the upper margin of the sternum; when the head is flexed, it is at the level of the upper border of the sternum or even below and behind it. The portion of the lateral lobe above the level of the superior border of the isthmus is called the \textit{upper horn}, the portion below the level of the inferior margin of the isthmus is called the \textit{lower horn}. The lower horn "is usually much smaller than the upper horn; frequently it is altogether absent."\textsuperscript{2}

At the inner and posterior part of each lateral lobe is the \textit{hilum}. At the hilum the inferior thyroid artery passes into the gland. "Here the \textit{recurrent laryngeal nerve} comes into close contact with the gland, lying in the space between it and the trachea and oesophagus."\textsuperscript{3}

The \textit{external} or \textit{superficial surface} is convex, and covered by the skin, the superficial fascia, the deep fascia, the Sterno-mastoid, the anterior belly of the Omo-hyoid, the Sterno-hyoid and Sterno-thyroid muscles, and beneath the last-named muscles by the pre-tracheal layer of the deep fascia, which forms a capsule for the gland.

The \textit{deep} or \textit{internal surface} is moulded over the underlying structures—viz., the thyroid and cricoid cartilages, the trachea, the inferior constrictor and posterior part of the Crico-thyroid muscles, the oesophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves.

The deep surface of each lobe is fixed by bands of fibrous tissue passing from the capsule of the isthmus and lateral lobes to the sides of the cricoid cartilage and the posterior fascia of the trachea. These bands are called the \textit{lateral} or \textit{suspensory ligaments}. Because of this fixation to the larynx and trachea by the capsule and by the lateral ligaments, the thyroid gland moves with the trachea and ascends during the act of swallowing. The recurrent laryngeal nerve on each side is in contact with the outer and posterior surface of the suspensory ligament.

The \textit{anterior border} is thin, and inclines obliquely from above downward and inward toward the middle line of the neck, while the \textit{posterior border} is thick and overlaps the common carotid artery. Each lobe is about two inches in length, its greatest width is about one inch and a quarter, and its thickness about three-quarters of an inch. The posterior border is over the common carotid artery and

\textsuperscript{1} Diseases of the Thyroid Gland. By James Berry.  
\textsuperscript{2} Ibid.  
\textsuperscript{3} Ibid.
touches the oesophagus and pharynx. The carotid artery usually makes a groove upon the gland.

The Isthmus (isthmus glandulae thyreoidea).—The isthmus connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea, but sometimes also the first and fourth rings. Its situation presents, however, many variations, a point of importance in the operation of tracheotomy. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the Sterno-hyoid muscle. Across its upper border run branches of the superior thyroid artery and vein; at its lower border is a branch of the inferior thyroid veins. Sometimes the isthmus is altogether wanting, the two lateral lobes being completely separate.

The third, pyramidal or middle lobe is called the pyramid of Lalouette. It is not constant, but is frequently found. Occasionally it arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly from the left lobe, and ascends in front of the thyroid cartilage in the direction of the middle of the hyoid bone. It may reach the bone or may not reach it. If it reaches the bone it is attached to it. If it does not reach the bone, fibrous tissue, which often contains muscle, is prolonged from the tip of the pyramid to the back of the bone or to the thyro-hyoid membrane. The pyramid is occasionally quite detached, or divided into two or more parts, or altogether wanting.

A few muscular bands, derived from the Thyro-hyoid muscles, are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle, which was named by Soemmerring the Levator glandulae thyreoidea.

Accessory Thyroids (glandulae thyreoideae accessoriae).—Frequently small isolated masses of thyroid tissue exist. They are found particularly about the lateral lobes of the thyroid gland in the sides of the neck or just above the hyoid bone, and are called accessory thyroids. Accessory thyroids may also exist by the side of the pyramidal lobe or upon the trachea, as low even as the level of the arch of the aorta. These isolated portions of gland tissue represent isolated portions of the median thyroid rudiment. Sometimes accessory thyroid tissue is found in the root of the tongue or in the interior of the larynx. Berry points out that a distinction must be made between true congenital accessory thyroids and masses of encapsuled thyroid tissue which "have been extruded from the gland."

Structure of the Thyroid (Fig. 998).—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance as a framework and imperfectly divides it into masses of irregular form and size, known as lobules. More slender septa separate the secretory alveoli from one another. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles or alveoli containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Baber, who has published some important observations on the minute structure of the thyroid,¹ the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (e.g., young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which are cubical or cylindrical. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of

¹ Researches on the Minute Structure of the Thyroid Glands, Phil. Trans., part iii., 1881.
which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the haemoglobin, which is thus set free from the colored corpuscles. This normal product is known as colloid material, and it is secreted by the epithelium. What part if any the colloid plays in the formation of the internal secretion of the gland is not known. It is quite possible that the colloid corresponds to the external secretion of glands with ducts and that the true internal secretion passes directly into the capillaries which form a network about the alveoli (Szymonowicz), or passes into the lymphatics. In the thyroid gland of the dog, Baber has found large round cells, parenchymatous cells, each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles. Between the thyroid vesicles in the human being are collections of round cells. They are, in reality, miniature vesicles, and are much more numerous in youth than in old age.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicles. These lymph-spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Small glands may be connected with this network. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

Vessels and Nerves.—The arteries (Figs. 392 and 393; see also p. 602) supplying the thyroid are the superior thyroid from the external carotid, and the inferior thyroid from the thyroid axis of the first part of the subclavian. Sometimes there is an additional vessel, the thyroidea media or ima, usually arising from the innominate artery, but sometimes from the arch of the aorta or the common carotid. It ascends upon the front of the trachea. The superior thyroid artery reaches the summit of the upper horn of the gland, and usually at this point gives off a vessel which courses down the posterior surface of the gland. The main trunk passes downward and inward at the junction of the inner and anterior border of the upper horn, giving branches to adjacent structures and sending branches over

![Diagram of thyroid gland vesicles](image)
The anterior surface of the thyroid gland. It reaches the isthmus and crosses the isthmus at its upper border to anastomose with the artery from the other side. The inferior thyroid artery, which is usually larger than the superior, after it has passed posterior to the sheath of the carotid and the sympathetic nerve, reaches the posterior surface of the gland. At this point branches are given off; some pass into the hilum; the others go to the posterior surface of the gland. The relation of the artery to the recurrent laryngeal nerve is very important to the surgeon. "Usually the main trunk of the artery passes behind the nerve; sometimes the artery breaks up before reaching the nerve; in this case one or more of the branches may pass in front of it. Much less commonly the main trunk or all its branches will be found to lie in front of the nerve." If the thyroid ima is present it goes to the lower part of the gland. The larger branches of the thyroid arteries are beneath the capsule and upon the surface of the gland; smaller branches pass to the interior of the gland (Berry). The arteries are remarkable for their large size and frequent anastomoses.

The thyroid veins (Figs. 447 and 448; see also p. 731) form a plexus upon the surface of the gland and beneath the capsule. Here and there veins pass through the capsule and go to adjacent venous trunks. Berry, accepting Kocher's description, notes the following veins: The superior thyroid vein runs with the superior thyroid artery and passes to the internal jugular vein. A transverse vein of the upper border of the isthmus joins the two superior thyroid veins. A single vein, the middle thyroid, sometimes emerges from the side of the gland and passes to the internal jugular. Usually, however, instead of this single vein there are two veins, the superior and inferior accessory thyroids. The superior accessory thyroid emerges from the outer side of the upper horn, below the apex, and passes to the internal jugular. The inferior accessory thyroid emerges from the posterior and inferior portion of the gland and passes to the internal jugular. The veins from the lower border of the gland vary greatly. A vein passes vertically down on each side in front of the trachea from the isthmus and from the inner side of the inferior horn. It is called by Kocher the thyroidea ima. The vein of the left side passes to the left innominate; the vein of the right side passes to the right innominate or left innominate. As Berry points out, the vein of one side may be small or may be absent, or the two veins may unite and form one vein which enters the left innominate. An inferior thyroid vein is often present. It is of small size, emerges at the inferior and external part of the gland, and passes to the corresponding innominate vein.²

The lymphatics are numerous and of large size. Collecting trunks arise from a network within the capsule. Some trunks ascend from the upper margin of the isthmus and reach the gland in front of the larynx; others ascend along the superior thyroid artery and reach the glands at the bifurcation of the carotid. Descending trunks from the lower margin of the isthmus reach the glands in front of the trachea; trunks from the side of the gland descend to the glands about the recurrent laryngeal nerve.³

The nerves are derived from the middle and inferior cervical ganglia of the sympathetic, and from the inferior laryngeal nerves. Probably there is also a branch from each superior laryngeal nerve.

Surgical Anatomy.—The thyroid gland may be congenitally absent, and when it is the individual suffers from the worst form of cretinism. One lobe may be congenitally absent, but this will provoke no trouble unless the other lobe undergoes atrophy.

Complete removal of the thyroid and parathyroids will produce operative myxedema (cachexia strumipriva), unless accessory thyroids enlarge and perform the functions of the thyroid.

The thyroid gland may be congenitally enlarged. The gland tends to atrophy in old age. It is atrophied in myxedema and cretinism. Some forms of thyroid enlargement are called goitre.

---

¹ Diseases of the Thyroid Gland. By James Berry.
² Ibid.
³ The Lymphatics. By Poirier, Cunéo, and Delamarre. Translated and edited by Cecil H. Leaf.
When all parts of the gland enlarge the condition is known as parenchymatous goitre.

Adenomatous goitre consists of an adenoma or of adenomata. In cystic goitre there is one or more cysts due to cystic degeneration of adenomata or to fusion of adjacent follicles.

A pulsating goitre is one which receives impulses from the carotid pulsations. In a fibroid goitre there is increase of interstitial connective tissue. A goitre which passes back of the sternum is known as substernal or intrathoracie. A goitre may extend back of the trachea or back of the oesophagus.

Exophthalmic goitre, Graves’s disease or Basedow’s disease, is a remarkable disease. Its three chief symptoms are enlargement of the thyroid, or goitre; prominence of the eyeballs, or exophthalmos, and very rapid pulse, or tachycardia. Dyspnœa, tremor, and various other symptoms are usually found. The thyroid gland may be the seat of a carcinomata or sarcomata (malignant goitre), syphilitic or tuberculous disease, ordinary inflammation, suppuration, or hydatid disease; For the relief of ordinary goitre various methods have been employed. Tapping, injection of astringents, simple incision, and the seton are obsolete. Ligature of the thyroid arteries is rarely performed as a curative measure. The superior and inferior thyroids of one side have been tied in some cases; all four thyroids in other cases. Jaboulay has performed extothyropexy. In this operation the gland is dislocated from its bed, brought out of the wound, and left exposed, in hope that it will atrophy

Division of the isthmus is occasionally practised to relieve dyspnœa. The operation sometimes succeeds, but often fails.

Extrirpation of one-half or two-thirds of the gland is a very successful operation. Removal of the entire gland with the parathyroids will be followed by operative myxoedema.

In extrirpating a lobe of the thyroid great care must be taken to avoid tearing the capsules, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured on the diseased side before an attempt is made to remove the mass, and in ligatureing the inferior thyroid the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature.

A cystic or solid tumor of the thyroid may be removed by intraglandular enucleation. If operation becomes necessary in exophthalmic goitre, partial extirpation is usually preferred. Bilateral extirpation of the cervical ganglia of the sympathetic (sympathectomy or Jonnesco’s operation) has been practised by some surgeons for exophthalmic goitre. The value of the procedure is uncertain.

Parathyroids (Fig. 999).—If the thyroid gland has been carefully detached, two round bodies of small size may be found embedded upon the trachea or upon the surface of the lateral lobe of the gland, between the terminal branches of the inferior thyroid artery. “These are the parathyroids, about the size of orange-seeds, and brownish-red in color.” These masses are constant in man and are more distinct in infants than in adults. Although the parathyroids lie on or in the thyroid, they are always completely separated from it by capsules of connective tissue. The parathyroids are divided from their situation into external and internal. The former, usually two in number, are situated, one on each side, in relation to the posertero-internal surface of the lateral lobe; sometimes they are duplicated. The latter, also usually two in number, are placed one in or on each lateral lobe, generally near its mesial surface.

Structure.—The structure of the parathyroids is different from that of the thyroid. They are composed of solid masses of epithelial cells arranged in a more or less columnar fashion with numerous intervening capillaries. The columns of the para-

---

1 Practical Anatomy. By Prof. Alfred W. Hughes.
There is much lymphoid tissue connected with the columns. Some regard the parathyroids as embryonic portions of the thyroid. This view seems to gain probability from the statement that after complete thyroidectomy, the parathyroids having been left, these structures increase in size, and apparently prevent operative myxœdema. If they are also removed, myxœdema arises. Nevertheless, MacCallum says "there is no histological proof that parathyroid tissue can ever become converted into thyroid tissue." Most observers regard the parathyroids as distinct glands possessed of a special function. Certain it is, as Gley and others have shown, removal of the parathyroids from herbivora leaving the thyroid intact is followed by spasms, tetany, etc., just as complete thyroidectomy is followed by such symptoms in carnivora.  

**THE THYMUS GLAND (Fig. 1000).**

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow and remains practically stationary until puberty, at which period it rapidly degenerates. It does not entirely disappear, for the shrunken and degenerated mass, even later in life, maintains a likeness to the original form and retains within its substance small portions of thymus tissue (Waldeyer). If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the level of the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sternohyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being

---

separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and are sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, is soft and is lobulated on its surfaces. It is about two inches in length, one and a half inches in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

**Structure** (Figs. 1001 and 1002).—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The **cortical portion** is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the **medullary portion** there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has made the important observation that haemoglobin is found in the thymus either in cysts or in cells situated near to or forming part of the concentric corpuscles. This haemoglobin varies from granules to masses exactly resembling colored blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing haemoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuscles.

**Vessels and Nerves.**—The arteries supplying the thymus are derived from the **internal mammary** and from the **superior** and **inferior thyroid**. The veins terminate in the two **innominate veins**, and in the **internal mammary** and the **thyroid veins**. The lymphatics are of large size, arise in the substance of the gland, and are said to terminate in the **internal jugular vein**. The **nerves** are
THE CAROTID GLAND OR CAROTID BODY (GLOMUS CAROTICUM).

This body, when present, lies in the carotid bifurcation, to the inner side of the common carotid below the bifurcation, or on the posterior surface of the internal or of the external carotid. It is often absent. It lies in fatty tissue and is surrounded by a fibrous capsule which is attached to the carotid sheath. The carotid gland is about the size of a grain of corn; it is oval in shape and reddish-brown in color. The capsule of the gland sends septa inward. The septa divide the organ into follicles or cell-balls. These cell-balls are composed of endothelial cells and are associated with blood capillaries. A branch (or branches) from the carotid artery enters the carotid gland, and the gland is closely connected with the carotid plexus of the sympathetic. (This structure has been recently studied by John Funke, Reclus and Chevasson, Paltauf, Kartschenko, and Marchand.)

Surgical Anatomy.—Tumors may arise from this structure. Such a tumor is apt to be above the level of the upper margin of the thyroid cartilage and in most cases it moves with each arterial beat.

1 American Medicine, vol. viii., No. 3.
THE DUCTLESS GLANDS

THE COCCYGEAL GLAND OR COCCYGEAL BODY OR LUSCHKA’S GLAND (GLOMUS COCCYGEUM).

Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka,¹ and named by him the coccygeal gland. Its most obvious connections are with the arteries of the part. It is similar in structure to the carotid body.

Structure.—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculae, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels “consists of the condensed and convoluted metameric dorsal arteries of the caudal segments embedded in tissue which is possibly a small persisting fragment of the neurenteric canal.” It resembles the carotid gland in structure, and is probably one of the ductless glands.

THE URINARY ORGANS.

THE KIDNEYS (RENEs) (Figs. 1003, 1004, 1005).

The Kidneys are large glands. They are two in number, and are situated in the back part of the abdomen, near the spinal column. Their function is to separate from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine. They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and are surrounded by a mass of fat and loose areolar tissue, which constitutes the fatty capsule (capsula adiposa) (Figs. 1008 and 1009). There are two distinct layers in this fatty capsule. The superficial fatty layer is the pararenal fat. Keen calls this layer the transversalis layer of fat, because it is derived from the transversalis fascia. The deeper and thicker perirenal layer is the true perinephric fat (Fig. 1009). The deeper layer of fat completely surrounds the kidney, and is somewhat adherent to the fibrous renal capsule. The fat about the kidney does

---

1 See Gerota, Arch. f. Anatomie, Leipzig, 1895; Zuckerkandl, Medizinische Jahrbücher, Vienna, 1883.
2 W. W. Keen, in American Medicine, January 31, 1903.
not look like fat in other regions, but is soft, delicate, and of a canary yellow color. These two layers are separated by a layer of connective tissue, which is the posterior layer of the perirenal fascia, and is called by Zuckerkandl the retro-renal fascia (fascia retrorenalis) (Fig. 1008). The true capsule of the kidney (tunica fibrosa) is thin, smooth, and glistening. The inner part of this capsule (tunica muscularis) contains unstriated muscle fibres. The true capsule can be easily separated from the underlying glandular structure. The upper extremity of the kidney is on a level with the upper border of the twelfth dorsal vertebra, the lower extremity on a level with the third lumbar vertebra (Fig. 1006). The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver. In the female the kidneys are a little lower than in the male.

Each kidney is about four and a half inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from 4½ ounces to 6 ounces; in the adult female, from 4 ounces to 5½ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has the characteristic form of a “flattened bean” (Spalteholz). It is flattened on its sides and presents at one part of its circumference a hollow. It is larger at its upper than at its lower extremity. The kidney presents for examination two surfaces, two borders, and an upper and lower extremity.

Surfaces. The Anterior Surface (facies anterior) (Figs. 1003 and 1004).—Its anterior surface is convex, looks forward and outward, and is partially covered by peritoneum. The right kidney in its upper three-fourths is in contact with the posterior part of the under surface of the right lobe of the liver. This area of the right kidney is flattened (impressio hepatica). Toward its inner border it is covered by the second part of the duodenum, while its lower and outer part is in relation with the hepatic flexure of the colon. The relation of the second part of the duodenum to the front of the right kidney is a varying one. The left kidney is covered above by the posterior surface of the stomach, below the stomach by the pancreas, behind which are the splenic vessels. The region in contact with the stomach is markedly depressed (impressio gastrica). Its lower half is in contact with some of the coils.
of the small intestine and sometimes with the third part of the duodenum. Near its outer border the anterior surface lies behind the spleen and the splenic flexure of the colon.

Fig. 1006.—Posterior surface of the kidneys. (Poirier and Charpy.)

Fig. 1007.—Relation of the kidney to the vertebral column, ribs, muscles, and lumbo-costal ligaments. (Poirier and Charpy.)
The kidneys are partly covered in front by peritoneum and partly uncovered. On the right kidney, the hepatic area, that is to say that portion of the kidney which produces the renal impression on the liver, is covered by peritoneum, which therefore separates the kidney from the liver; the duodenal and colic areas are not peritoneal, and these structures are connected to the kidney by loose connective tissue; at the lower and inner extremity is a small area, the mesocolic area, which is covered by a layer of peritoneum of the greater sac and by the colic vessels. On the left kidney the gastric area is covered by the peritoneum of the lesser sac; the pancreatic and colic areas are non-peritoneal; while, as on the right side, at the lower and inner extremity, is an area, mesocolic area, which is covered by the peritoneum of the greater sac and by the colic vessels.

The Posterior Surface (facies posterior) (Fig. 1005).—The posterior surface of the kidney is flatter than the anterior and is directed backward and inward. It is entirely devoid of peritoneal covering, being embedded in areolar and fatty tissue. It lies upon the Diaphragm, the anterior layer of the lumbar aponeurosis, the external and internal arcuate ligaments, the Psoas and Transversalis muscles, one or two of the upper lumbar arteries, the last dorsal, ilio-hypogastric, and ilio-inguinal nerves. The lumbo-costal ligaments overlie the posterior surface of the kidney (Fig. 1007). The right kidney rests upon the twelfth rib (Fig. 1007), the left usually on the eleventh and twelfth ribs. The Diaphragm separates the kidney from the pleura as the pleura dips down to form the phrenico-costal sinus (Fig. 987), but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the external arcuate ligament, and when this is the case the perirenal areolar tissue is in immediate apposition with the diaphragmatic pleura. In the lower part of the posterior surface of the kidney is an impression produced by the Quadratus lumborum muscle and called
the impressio muscularis. A little internal to this a flattening, caused by the Psoas muscle, is often recognizable. At the upper part of the posterior surface is a sulcus produced by contact with the Diaphragm.

Borders. The External Border (margo lateralis) (Figs. 1004 and 1005).—The external border is convex, and is directed outward and backward, toward the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen (Fig. 1003).

The Internal Border (margo medialis) (Figs. 1004 and 1005).—The internal border is concave, and is directed forward, inward, and a little downward. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the hilum (hilus renalis) (Fig. 1010), and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

Extremities. The Superior Extremity (extremitas superior) (Figs. 1004 and 1005).—The superior extremity, directly slightly inward as well as upward, is thick and rounded, and is surrounded by the suprarenal capsule (Fig. 1010), which covers also a small portion of the anterior surface.

The Inferior Extremity (extremitas inferior) (Figs. 1004 and 1005).—The inferior extremity, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part (Fig. 1005). By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter behind and below the other vessels; the hilum will then be directed to the side to which the kidney belongs.

General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue (tunica fibrosa), which forms the firm, smooth, true capsule covering the entire organ. The capsule passes over the margins of the hilum, enters the interior of the kidney, and covers the wall of the sinus. The true capsule is closely and firmly adherent to the renal pelvis where it is attached to the sinus. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue which pass to the intrarenal connective tissue and numerous small blood-vessels are torn through. Beneath this fibrous layer a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the true capsule is stripped off, the surface of the kidney is found to be smooth, even, and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland (Fig. 1027). The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed around the vessels and the excretory duct (Fig. 1010). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance. This central cavity is called the sinus (sinus renalis), and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the hilum (hilus renalis) (Fig. 1010), which is situated at that part of the cavity which is not surrounded by kidney structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus (Fig. 1004). The excretory duct or ureter, after entering, dilates into a wide, funnel-shaped sac named the pelvis (pelvis renalis) (Figs. 1010 and 1011). This divides into two or three tubular divisions, which subdivide into several short,
truncated branches named calices or infundibula (calyces renales), all of which are contained in the central cavity of the kidney (Figs. 1010 and 1011). The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance (Fig. 1011).

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz., of an external granular investing part, which is called the cortical portion (substantia corticalis); and of an internal part, the medullary portion (substantia medullaris), made up of a number of dark-colored pyramids, with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillae, the renal papillae (papillae renales), which project into the interior of the calices (Fig. 1010).

The cortical substance (Figs. 1010 and 1017) is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. Prolongations of the cortical substance pass between the pyramids toward the renal sinus. These prolongations are the cortical columns or the columns of Bertin (columnae renales) (Fig. 1010, B B). The columns contain blood-vessels, nerves, and lymphatics. The base of each pyramid (basis pyramidis) is known as the intermediate zone. That portion of the cortical substance which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (marked by the dotted line extending from A to A' in Fig. 1010), is called a cortical arch, the depth of which varies from a third to half an inch.

The medullary substance (Figs. 1010 and 1017), as before stated, is seen to consist of red-colored, striated, conical masses, the pyramids of Malpighi (pyramides
The Malpighian pyramids (Fig. 1010), the number of which, varying from eight to eighteen, corresponds to the number of lobes of which the organ in the fetal state is composed. The pyramids are composed of straight tubes which pass between the apices of the papillae and the cortical margin. They enter the cortex in masses called the **pyramids of Ferrein** (see below). The sides of the pyramids of Malpighi are contiguous with the cortical columns, while the apices, known as the **papillae of the kidney** (**papillae renales**), project into the calices of the ureter, each calyx receiving two or three papillae. Radiating from the bases of the pyramids of Malpighi are ridges of cortical substance with distinct depressions between them. These ridges are the **medullary rays** (**pars radiata**) or **pyramids of Ferrein** (Figs. 1013 and 1017). The **labyrinth of the cortex** (Fig. 1013) is constituted by the kidney substance between the rays. The pyramids of Ferrein look like direct continuations of the medullary substance, but, in reality, they are in the cortex, and are formed by the straight tubes extending in masses into the cortex. The pyramids of Ferrein are much smaller than the pyramids of Malpighi. In the columns of Bertin blood-vessels, nerves, and lymphatics pass to and emerge from the sinus by way of small foramina. The summit of a papilla contains a number of orifices of papillary ducts. Such an area is called an **area cribrosa** (Fig. 1014).

These two parts, **cortical** and **medullary**, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

**Minute Anatomy.**—The **uriniferous tubes**, **urinary canals** or **tubuli uriniferi** (**tubuli renales**) (Figs. 1012 and 1017), of which the kidney is for the most part made up, commence in the cortical portion of the kidney. Each tubule begins between the medullary rays (Fig. 1013) in a sac, Bowman’s capsule or the Malpighian capsule (see below). The tubules, as a rule, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths, so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillae is examined with a lens, it will be seen to be studded over with a number of small depressions (**foramina papillaria**), from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the **tubuli uriniferi**, which terminate in this situation. The tubuli uriniferi begin in the cortex as the **Malpighian bodies** or **corpuscles** (**corpuscula renis**) (Figs. 1012, 1013, 1015, 1016, and 1018), which are small rounded masses, varying in size, but average about \( \frac{1}{150} \) of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a **Malpighian tuft**, and a membranous envelope, the **Malpighian capsule** or **capsule of Bowman** (**capsula glomeruli**), which latter is a small pouch-like commencement of a uriniferous tubule.

The **Malpighian Tuft** or **Vascular Glomerulus** (Figs. 1015, 1016, 1017, 1022, and 1023) is a network of convoluted capillary blood-vessels held together by scanty
connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the **afferent vessel**, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the resulting **efferent vessel** emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 1015). The **Malpighian** or **Bowman's capsule** (*capsula glomeruli*) (Figs. 1015, 1016, and 1017), which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface with a layer of squamous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (Fig. 1016). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in the adult, but in the foetus and young subject they are polyhedral or even columnar.

The **Tubuli Uriniferi**, commencing in the Malpighian bodies, in their course present many changes in shape and direction (**tubuli renales contorti**), and are
contained partly in the medullary and partly in the cortical portions of the organ. At the junction of a tubule with the Malpighian capsule there is a somewhat constricted portion which is termed the neck (Fig. 1018). Beyond this the tubule becomes convoluted, and pursues a considerable course in the cortical structure, constituting the proximal or first convoluted tubule (Figs. 1017 and 1018). After a time the convolutions disappear, and the tubule approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tubule has been called the spiral tube of Schachowa (Fig. 1018). Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction (tubuli renales recti), and each tubule dips down for a variable depth into the pyramids, constituting the descending limb of Henle's loop (Figs. 1017 and 1018). Bending on itself, it forms a kind of loop near the apex of the pyramid, the loop of Henle, and, reascending, becomes suddenly enlarged and again spiral in direction, forming the ascending limb of Henle's loop (Figs. 1017 and 1018), and re-enters the cortical structure. This portion of the tubule does not present a uniform calibre, but becomes narrower as it ascends and irregular or somewhat spiral in outline (Fig. 1018). As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the irregular tubule (Fig. 1018); it terminates in a convoluted tubule which exactly resembles the proximal convoluted tubule; and is called the distal or second convoluted tubule (Figs. 1017 and 1018). This again terminates in a narrow curved or junctional tubule, which enters the straight or collecting tube.

Each straight collecting or receiving tube (Figs. 1012, 1017, and 1018) commences by a small orifice on the summit of a papilla, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ,
and the bases are applied to the medullary portion. These are termed the medullary rays or the pyramids of Ferrein (Fig. 1013; also p. 1417). As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies. Each collecting tube receives a number of tubules, and several collecting tubes unite together to form a papillary duct (Fig. 1017) and open by a foramen (Fig. 1014) at the surface of the papilla.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine,
the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. To recapitulate: the tube first presents a constricted portion, (1) the neck. 2. It forms a wide convoluted tube, the proximal convoluted tube. 3. It becomes spiral, the spiral tubule of Schachowa. 4. It enters the medullary structure as a narrow, straight tube, the descending limb of Henle's loop. 5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the ascending limb of Henle's loop. 6. It now becomes irregular and angular in outline, the irregular tubule. 7. It then becomes convoluted, the distal convoluted tubule. 8. Diminishing in size, it forms a curve, the curved or junctional tubule. 9. Finally, it joins a straight tube, the straight collecting tube, which is continued downward through the medullary substance and joins other straight tubes to form a papillary duct, which opens in a foramen at the apex of a pyramid.

**Fig. 1018.**—Uriniferous tube. For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

**Fig. 1019.**—Longitudinal section of Henle's descending limb: a, membrana propria; b, epithelium.

**Fig. 1020.**—Longitudinal section of straight tube: a, cylindrical or cubical epithelium; b, membrana propria.

**The Tubuli Uriniferi: their Structure** (Figs. 1019, 1020, and 1021.)—The tubuli uriniferi consist of basement-membrane lined with epithelium. The

1 From Handbook for the Physiological Laboratory.
epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus (Fig. 1016). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement-membrane unlined with epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement-membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement-membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation. In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Fig. 1019). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 1021). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen. In the irregular tubule the cells undergo a still further change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules. In the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance. In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral.

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Fig. 1020), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes.
The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery (Figs. 422, 423, 1005, and 1011), a large offset of the abdominal aorta. Previously to entering the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off a small branch to the suprarenal capsules, the ureter, and the surrounding cellular tissue and muscles. It has been pointed out by Hyrtl (p. 679) that the renal artery gives off a branch which divides and supplies the dorsal portion of the kidney and a branch which divides and supplies the ventral portion of the kidney (Figs. 422 and 423). Between these two vascular systems is a non-vascular zone, called by Byron Robinson the exsanguinated renal zone of Hyrtl (Figs. 422 and 423). It “is one-half inch dorsal to the lateral longitudinal renal border.” Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the inferior renal artery. The branches of the renal arteries pass to the kidney substance between the pyramids and are known as interlobar arteries (arteriae interlobares renis) (Figs. 1013, 1017, 1024, and 1025). At the junction of the cortical and medullary portions these vessels turn and for a short distance pursue a course parallel to the kidney surface. There are thus formed a series of incomplete vascular arches across the bases of the pyramids, the arcuate arteries (arteriae arciformes) (Figs. 1017, 1022, and 1023). From these arches two sets of vessels come. The vessels of one set go to the periphery and enter the labyrinth, those of the other set pass toward the centre and enter the intermediate zone of the medulla. These last vessels are the arteriolas recti (Figs. 1017, 1022, and 1023). Because of these vessels the kidney exhibits striations on section. Each of the arteriolas recti in the medulla divides into numerous small branches which are nearly parallel to each other and supply the tubules of this region. The arteries which arise from the arches and pass to the periphery are the interlobular arteries (arteriae interlobares) (Figs. 1017, 1022, 1023, and 1026). They traverse the labyrinth and pass toward the surface of the kidney. A number of short branches, the vasa afferentia, are given off by the interlobular arteries (Figs. 1017, 1022, 1023, and 1026). Each afferent vessel passes to a capsule of Bowman. On reaching the capsule the vessel forms a capillary mass, the glomerulus, which is within the invaginated capsule (Figs. 1016, 1017, 1023, and 1026).

1 Byron Robinson, p. 679.
Emerging from each glomerulus is a small vessel, the *vas efferens* (Fig. 1015, 1016, 1017, 1023, and 1026). This vessel divides into capillaries which are distributed to the tubules of the labyrinth and medullary rays. Blood is gathered from the capillaries about the tubules by veins which correspond to the interlobular arteries and arteriolae recti. These veins form a set of arcs across the bases of the pyramids. From the arches veins arise and pass between the pyramids to the sinus of the kidney, where they unite and form branches of the renal vein.

**Nerves of the Kidney.**—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the *renal plexus*, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

**The Lymphatics.**—The lymphatics consist of a *superficial* and *deep set*. The superficial lymphatics are just beneath the capsule. From them come two sets of collecting trunks (Sappey). One set joins the deep collectors by entering the kidney substance or passing to the hilum. Another set pass into the lymphatics of the fatty capsule.

The deep collectors emerge from the hilum and lie about the renal artery and vein. From the right kidney some of the trunks pass to the glands about the vena cava and possibly also in the glands in front of the aorta. Others end in the glands back of the vena cava (Stahr).

From the left kidney the trunks pass to the glands which lie along the left side of the abdominal aorta. The lymphatics of the fatty capsule of the kidney pass to the same glands as do the deep collectors of the kidney (Stahr).

**Connective Tissue or Intertubular Stroma.**—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

**Variations and Abnormalities.**—Congenital absence of the kidney has been observed. Not unusually one kidney is considerably larger than the other; occasionally one is very large and the other is very small, from atrophy, the large organ having become large in response to a functional need, which causes it to compensate for the insufficiency of the small kidney. If a kidney is removed surgically, the other kidney enlarges. As previously stated, the kidneys of the fetus and of the young child show distinct fissures which makes each organ lobulated (Fig. 1027). The adult kidneys frequently exhibit remains of these fissures. A *horseshoe kidney* is a condition in which the lower poles of the two kidneys are united by kidney structure, the bond of union crossing the middle line. The strip of kidney tissue which effects the junction may be slight in amount.

---

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
considerable, or extensive. Sometimes the two kidneys are completely fused together into one large organ with two ureters.

**Surface Form.**—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly:* "1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—i. e., between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. *Posteriorly:* The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch below. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for two and three-quarter inches. 3. A line from the lower end of the first transversely outward for two and three-quarter inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

**Surgical Anatomy.**—Cases of congenital absence of a kidney, of atrophy of a kidney, and of horseshoe kidney are of great importance, and must be duly taken into account, when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be only joined together at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disk-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher or lower than normal or removed farther from the spine than usual or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed. It is then known as a floating kidney. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum, which then passes backward to the spine as a double layer, forming a mesonephron, which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, either moving in or moving with its fatty capsule. This condition is known as movable kidney (nephroptosis), and is more common in the female than in the male, and on the right than the left side. If a displaced kidney becomes fixed in an abnormal position, it is said to be dislocated. Movable kidney cannot be distinguished from floating kidney until the kidney is exposed by incision. Other malformations are the persistence of the foetal lobulation; the presence of two pelves or two ureters to the one kidney. In some rare instances a third kidney may be present.

The kidney is embedded in a large quantity of loose fatty tissue, and is but partially covered by peritoneum; hence, rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is, in the majority of cases, outside the peritoneal cavity. Occasionally the kidney may be bruised by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient hematuria, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follows.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting perinephritic abscesses. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess may burst into the pleura, causing empyema; into the colon or bladder; or may point externally in the groin or loin. *Tumors of the kidney,* of which, perhaps, sarcoma in children is the most common, may be recognized by their position and fixity; by the resistant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The *examination of the kidney* should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while
The URINARY ORGANS

the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation and some faintness.

The kidney has, of late years, been frequently attacked surgically. It may be exposed and opened for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when wounded (nephorrhaphy); it may be fixed in place by sutures (nephropexy) or gauze pads when movable or floating; or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The operation is best performed by a lumbar incision, except in a case of very large tumor or of wandering kidney with a loose mesonephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique a vertical, or a transverse incision. A common incision for exposing the kidney begins an inch below the twelfth rib at the margin of the Erector spinae muscle and passes obliquely downward and forward, exposing the anterior border of the Latisimus dorsi and the posterior border of the Internal oblique. The surgeon divides the posterior leaflet of the lumbar fascia, draws aside or incises the Quadratus lumborum, and cuts the anterior leaflet of the lumbar fascia and also the transversalis fascia. He opens the fatty capsule down to the kidney and strips it from the true capsule, bringing the kidney outside of the body for inspection. The vertical incision at the edge of the Erector spinae muscle is frequently used. A gridiron or muscle-splitting operation is used by some in order to avoid the division of nerves, vessels, and muscular fibre.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with.· If the incision were made in the linea alba, the kidney would be reached from the inner side of the colon, and the vessels running to supply the colon would necessarily be interfered with. The incision is made of varying length according to the size of the kidney, and commences just below the costal arch. The abdominal cavity is opened. The intestines are held aside, and the outer layer of the mesocolon incised, so that the fingers can be introduced behind the peritoneum and the renal vessels, are sought for. These vessels are then to be ligatured; if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and the ureter divided, and the latter disinfected and tied, and, if it is thought necessary, stitched to the edge of the wound.

THE URETER (Figs. 1004, 1005, 1006, 1011, 1028, 1029).

The ureters are the two tubes which conduct the urine from the kidneys into the bladder. The ureter commences within the sinus of the kidney by a number of short truncated branches, the calices or infundibula, which unite either directly or indirectly to form a dilated pouch, the pelvis (Fig. 1010), from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The calices are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillae, their number is generally less than the pyramids themselves. The calices vary in number from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the pelvis or dilated portion of the ureter. The portion last mentioned, where the pelvis merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (Fig. 1006).

The Ureter Proper.—The ureter proper is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the pelvis of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region (pars abdominalis) (Fig. 1029), into the cavity of the pelvis (pars pelvina) (Fig. 1029), where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice (orificium ureteris) (Fig. 1045), after having passed obliquely for nearly an inch between its muscular and mucous coats (Fig. 1028). The lower part of the abdominal portion of the ureter exhibits a spindle-shaped dilatation.

Relations (Fig. 1029).—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the
spermatic vessels; the right ureter is crossed by the branches of the mesenteric arteries, which are distributed to the ascending colon, and the left ureter by those for the descending colon; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery and vein, lying behind the ilium on the right side and behind the sigmoid flexure of the colon on the left side. In the pelvis it enters the posterior false ligament of the bladder, below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter is to the inner side of the uterine artery at the wall of the pelvis, it passes forward and inward below the posterior layer of the broad ligament running through the parametrium, passing along the side of the neck of the uterus and upper part of the vagina, being in contact with the anterior and lateral vaginal walls and being crossed anteriorly by the uterine artery (Fig. 1099). At the base of the bladder the ureter is situated about two inches from its fellow: lying, in the male, about an inch and a half from the vesical orifice of the urethra, at one of the posterior angles of the trigone (Fig. 1045).

**Structure.**—The ureter is composed of three coats—fibrous, muscular, and mucous.

The Fibrous Coat (*tunica adventitia*).—The fibrous coat is the same throughout the entire length of the duct, being continuous at one end with the fibrous capsule of the kidney at the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.
The Muscular Coat (tunica muscularis).—In the pelvis of the kidney the muscular coat consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillae at the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal (stratum externum), a middle circular (stratum medium), and an internal layer (stratum internum), less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The Mucous Coat (tunica mucosa).—The mucous coat is smooth, and presents a few longitudinal folds which become effaced by distention. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillae of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of transitional epithelium. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with concave margins on their outer surface, into which fit the rounded ends of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement-membrane.

Vessels and Nerves.—The arteries supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical. The nerves are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

Surgical Anatomy.—Subcutaneous rupture of the ureter is not a common accident, but occasionally occurs from a sharp, direct blow on the abdomen, as from the kick of a horse. The ureter may be either torn completely across, or only partially divided, and, as a rule, the peritoneum escapes injury. If torn completely across the urine collects in the retroperitoneal tissues; if it is not completely divided, the lumen of the tube may become obstructed and hydro-nephrosis or pyo-nephrosis results. The ureter may be accidentally wounded in some abdominal operations; if this should happen, the divided ends must be sutured together, or, failing to accomplish this, the upper end must be implanted into the bladder or the intestine.

THE SUPRARENAL CAPSULE OR GLAND (GLANDULA SUPRARENALIS) (Figs. 1010, 1030, 1031).

The suprarenal capsules belong to the class of ductless glands. They are two small flattened bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one (Fig. 1030) is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left (Fig. 1031) is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is from one to one and a half drachms each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body.

The Right Suprarenal (Fig. 1030).—The right suprarenal is roughly triangular in shape, its angles pointing upward, downward, and outward. It presents two surfaces for examination, an anterior and a posterior. The anterior surface (facies
anterior) presents two areas, separated by a furrow, the hilum (hilus glandulae suprarenalis): one area occupying about one-third of the whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the posterior surface of the right lobe of the liver, and along its inner border with the inferior vena cava; the remaining area is elevated, and is divided into a non-peritoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by peritoneum forming the hepato-renal fold. The posterior surface (facies posterior) is slightly convex, and rests upon the Diaphragm. The base (basis glandulae suprarenalis) is concave, and is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The Left Suprarenal (Fig. 1031).—The left suprarenal is crescentic in shape, its concavity being adapted to the upper end of the left kidney. It presents an inner border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its anterior surface (facies anterior) presents two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. A hilum is present, as in the right suprarenal. Its posterior surface (facies posterior) presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, while the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Accessory Suprarenal Glands (glandulae suprarenales accessoriae).—Small accessory suprarenals are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure (Figs. 1032, 1033, and 1034).—On making a perpendicular section (Fig. 1032), the suprarenal gland is seen to consist of two substances—external or cortical and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep-yellow color. The medullary substance is soft, pulpy,
and of a dark-brown or black color, whence the name atrabiliary capsules formerly given to these organs. In the centre is often seen a space, not natural, but formed by breaking down after death of the medullary substance.

The Cortical Portion (substantia corticalis) (Fig. 1032).—The cortical substance consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the zona glomerulosa; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise,

the zona fasciculata. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the zona reticularis. These processes or trabeculae, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not infrequently fat-globules. These groups of cells do not entirely fill the spaces in which they are contained, but between them and the trabeculae of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the
group. The lymph-path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

The Medullary Portion (substantia medullaris) (Fig. 1032).—In the medullary portion the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla; this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

Vessels and Nerves.—The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerge as a single vessel from the centre of the gland.

The arteries supplying the suprarenal capsules are three in number and of large size; they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The suprarenal vein returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it emerges from the hilum and opens on the right side into the inferior vena cava, on the left side into the renal vein.

The lymphatics form several collections which are about the beginning of the suprarenal vein. They terminate in the glands to the corresponding side of the aorta.

The nerves are exceedingly numerous, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and pneumogastric nerves. They enter the lower and inner part of the capsule, traverse the cortex, and terminate about the cells of the medulla. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE CAVITY OF THE PELVIS.

The cavity of the pelvis is that part of the general abdominal cavity which is below the level of the ilio-pectineal lines and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Pyriformis muscles, and the great sacro-sciatic ligaments; in front and at the sides by the portions of the innominate bones below the ilio-pectineal lines. In front and to the sides the bony sides of the pelvic cavity are partly covered by the internal Obturator muscles, and internal to these muscles by the parietal part of the pelvic fascia. Above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the urinary bladder, the rectum, and some of the generative organs peculiar to each sex, and some convolutions of the small intestines. The pelvic viscera are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.
THE URINARY BLADDER (VESICA URINARIA) (Figs. 1037, 1038, 1054, 1055).

The urinary bladder is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distention of the organ. During infancy it is conical in shape, and projects above the symphysis pubis into the hypogastric region. In the adult, when quite empty and contracted (Figs. 1035 and 1036), it is cup-shaped, and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is
placed deeply in the pelvis, flattened from before backward, and reaches as high as the upper border of the symphysis pubis. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity (Fig. 1036), and when greatly distended (Figs. 1036 and 1037), it is ovoid in shape, rising into the abdominal cavity, and often extending nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the symphysis pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its capacity is said to be greater than in the male.1 When moderately distended, it measures about five inches in length, and three inches across, and the ordinary amount which it can contain without serious discomfort is about a pint.

The bladder is divided for purposes of description into a superior, an anteroinferior, and two lateral surfaces, a base or fundus, and a summit or apex.

Surfaces. The Superior or Abdominal Surface (Figs. 852, 1037, 1038, and 1055).

1 According to Henle, the bladder is considerably smaller in the female than in the male.—Ed. of 15th English edition.
peritoneum. It looks almost directly upward into the abdominal cavity, and extends in an antero-posterior direction from the apex to the base of the bladder. It is in relation with the small intestine and sometimes with the sigmoid flexure, and, in the female, with the uterus. On each side, in the male, a portion of the vas deferens is in contact with the hinder part of this surface, lying beneath the peritoneum.

The Antero-inferior or Pubic Surface (Figs. 1037, 1038, and 1055).—The antero-inferior or pubic surface looks downward and forward. In the undistended condition it is uncovered by peritoneum, and is in relation with the Obturator internus muscle on each side, with the recto-vesical fascia, and anterior true ligaments of the bladder. It is separated from the body of the pubis by a triangular interval, the space of Retzius, occupied by fatty tissue. As the bladder ascends into the abdominal cavity during distention the distance between its apex and the umbilicus is necessarily diminished, and the urachus (Fig. 852 and 1055) is thus relaxed; so that, instead of passing directly upward to the umbilicus, it descends first on the upper part of the anterior surface of the bladder, and then, curving upward, ascends on the back of the abdominal wall. The peritoneum, which follows the urachus, thus comes to form a pouch (plica vesicalis transversa) of varying depth between the anterior surface of the viscus and the abdominal wall (Fig. 1038). The fold passes to the neighborhood of the internal abdominal rings. Thus, when the bladder is distended, the upper part of its anterior surface is in relation with the urachus and is covered by peritoneum. The lower part of its anterior surface, a distance of about two inches above the symphysis pubis, is devoid of peritoneum, and is in contact with the abdominal wall.
The Lateral Surfaces.—The lateral surfaces are covered behind and above by peritoneum, which extends as low as the level of the obliterated hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from the Levatores ani muscles and walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the recto-vesical fascia by a broad expansion on either side, the lateral true ligaments. The vas deferens crosses the hinder part of the lateral surface obliquely, and passes between the ureter and the bladder. When the bladder is empty the peritoneum descends on the pelvic wall as low as the lateral border of the bladder and enters a groove known as the paravesical fossa. The lateral surfaces, the pubic surface, and the abdominal surface together constitute the body of the bladder (corpus vesicae).

The Fundus or Base (fundus vesicae)(Figs. 1038, 1052, and 1055).—The fundus or base is directed downward and backward, and is partly covered by peritoneum and is in part not covered by it. In the male the upper portion, to within about an inch and a half of the prostate, is covered by the recto-vesical pouch of peritoneum (Fig. 855). The lower part is in direct contact with the anterior wall of the second part of the rectum and the vesiculae seminales and vasa deferentia (Figs. 1052 and 1054). The ureters enter the bladder at the upper part of its base, about an inch and a half above the base of the prostate gland (Fig. 1045).

The portion of the bladder in relation with the rectum corresponds to a triangular space, bounded, below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; and on each side, by the vesicula seminalis and vas deferens. It is separated from direct contact with the rectum by the rectovesical fascia. When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. In the female, the base of the bladder is connected to the anterior aspect of the cervix uteri by areolar tissue, and is adherent to the anterior wall of the vagina (Fig. 853). Its upper surface is separated from the anterior surface of the body of the uterus by the utero-vesical pouch of the peritoneum (Fig. 853).

The so-called neck or cervix of the bladder (collum vesicae) is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck, but the bladder suddenly contracts to the opening of the urethra (Fig. 1038). In the male it is surrounded by the prostate gland and its direction is oblique when the individual is in the erect posture (Figs. 1037 and 1038). In the female its direction is obliquely downward and forward.

The Summit or Apex (vertex vesicae).—The summit or apex is the portion of the bladder which when that organ is empty or nearly empty is nearest to the upper border of the symphysis. It is directed upward and forward. In a distended bladder the apex is well above the pubes in the abdominal cavity.

The Urachus or Middle Umbilical Ligament (ligamentum umbilicale medium) (Fig. 1055).—The urachus is a connective-tissue cord and is the obliterated remains of the tubular canal of the allantois, which existed in the embryo, and a portion of which expanded to form the bladder. It passes upward, from the apex of the bladder, between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscular fibres. The urachus causes the formation of a peritoneal fold, the plica umbilicalis media (Fig. 852). On each side of it is placed a fibrous cord, the obliterated portion of the hypogastric artery, which, passing upward from the side of the bladder, approaches the urachus above its summit. Over each cord is the fold known as the plica umbilicalis lateralis (Fig. 852). In the infant, at birth, the urachus is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.
Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The two anterior true ligaments, the pubo-prostatic or pubo-vesical ligaments (ligamenta puboprostatica) extend from the back of the ossa pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland. These ligaments are formed by the recto-vesical fascia, and contain a few muscular fibres prolonged from the bladder.

The two lateral true ligaments, formed by expansions from the fascia lining the lateral wall of the pelvis, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate gland and to the sides of the base of the bladder.

The urachus or middle umbilical ligament is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The two posterior false ligaments pass forward, in the male, from the sides of the rectum (plicae rectovesicales); in the female, from the sides of the uterus (plicae rectouterinae), to the posterior and lateral aspect of the bladder; they form in the male the lateral boundaries of the recto-vesical pouch (excavatio rectovesicalis) (Figs. 926 and 1038); they form in the female the lateral boundaries of the pouch or cul-de-sac of Douglas (excavatio rectouterina [Douglasii]) (Figs. 853 and 927). The posterior false ligaments contain the obliterated hypogastric arteries and the ureters, together with vessels and nerves. In the base of each fold is smooth muscle-fibre, the Recto-vesical muscle (m. rectovesicalis).

The two lateral false ligaments are reflections of the peritoneum, from the iliac fossae and lateral walls of the pelvis to the sides of the bladder. Each lateral false ligament (ligamentum umbilicale laterale) passes in front into the plica umbilicalis lateralis over the corresponding hypogastric artery. The two lateral reflections of peritoneum are continuous in front of the apex vesicae, at which point the peritoneum passes upon the urachus.

The superior or anterior false ligament or the suspensory ligament (plica umbilicalis media) is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It is carried off from the bladder by the urachus and the
obliterated hypogastric arteries. The peritoneal fold over each obliterated hypo-
ogastric artery is called the plica umbilicalis lateralis (Fig. 852), and is the pro-
longation forward of the ligamentum umbilicalle laterale. Besides the true and
false ligaments, the bladder receives support from the fibrous tissue and unstriated
muscle about the seminal vesicles, and terminations of the ureters and vasa defer-
entia. In the female the connection with the anterior vaginal wall supports the
base of the bladder. In both sexes the most solidly fixed part of the bladder is
about the orifice of the urethra.

Structure.—The bladder is composed of four coats—serous, muscular, sub-
mucous, and mucous.

The Serous Coat (tunica serosa).—The serous coat is partial, and derived from
the peritoneum. It invests the superior surface and the upper part of the lateral surfaces
and base, and is reflected from these parts on to the abdominal and pelvic walls.

The Muscular Coat (tunica muscularis) (Figs. 1040, 1041, and 1042).—The mus-
cular coat consists of three layers of unstriped muscular fibre: an external layer,
composed of fibres having for the most part a longitudinal arrangement; a middle
layer, in which the fibres are arranged, more or less, in a circular manner; and an
internal layer, in which the fibres have a general longitudinal arrangement.

The fibres of the external longitudinal layer (stratum externum) arise from the
posterior surface of the body of the os pubis in both sexes (m. pubovesicalis), and
in the male arise also from the adjacent part of the prostate gland and its capsule.
They pass, in a more or less longitudinal manner, up the anterior surface of the
bladder, over its apex, and then descend along its posterior surface to its base,
where they become attached to the prostate in the male and to the front of the vagina
in the female. At the sides of the bladder the fibres are arranged obliquely and
intersect one another. The external longitudinal layer has been named the
Detrusor urinae muscle.

The middle circular layers (stratum medium) are very thinly and irregularly
scattered on the body of the organ, and, though to some extent placed transversely
to the long axis of the bladder, are for the most part arranged obliquely. Toward
the lower part of the bladder, round the neck and the commencement of the
urethra, they are disposed in a thick circular layer, forming the sphincter vesicae,
which is continuous with the muscular fibres of the prostate gland.

The internal longitudinal layer (stratum internum) is thin, and its fasciculi have
a reticular arrangement, but with a tendency to assume for the most part a longi-
tudinal direction. Two bands of oblique fibres, originating behind the orifices of
the ureters, converge to the back part of the prostate gland, and are inserted, by
means of a fibrous process, into the middle lobe of that organ. They are the
muscles of the ureters, described by Sir C. Bell, who supposed that during the con-
traction of the bladder they served to retain the oblique direction of the ureters,
and so prevent the reflux of the urine into them.

The Submucous Coat (tela submucosa).—The submucous coat consists of a layer of
areolar tissue connecting together the muscular and mucous coats, and inti-
mately united to the latter.

The Mucous Coat (tunica mucosa).—The mucous coat is thin, smooth, and of a
pale rose color. It is continuous above through the ureters with the lining mem-
brane of the uriniferous tubes, and below with that of the urethra. Except at the
trigone, it is connected very loosely to the muscular coat by a layer of areolar tissue,
and is therefore thrown into folds or rugae when the bladder is empty (Fig.
1046). The mucous membrane over the trigone never presents rugae. The
epithelium covering it is of the transitional variety, consisting of a superficial
layer of polyhedral flattened cells, each with one, two, or three nuclei (Fig. 1043);
below these is a stratum of large club-shaped cells with the narrow extremity of
each cell directed downward and wedged in between smaller spindle-shaped cells,
each an oval nucleus (Fig. 1044). There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

**Objects Seen on the Inner Surface.**—Upon the inner surface of the bladder are seen the mucous membrane, orifices of the ureters, the trigone, and the commencement of the urethra.

![Fig. 1043.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)](image1)

![Fig. 1044.—Deep layers of epithelium of bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)](image2)

**The Mucous Membrane.**—The mucous membrane of the empty bladder is thrown into folds or rugae, except over the trigone, where it is firmly adherent to the muscular coat and is smooth (Figs. 1045 and 1046). The folds disappear when the bladder is distended.

**The Orifices of the Ureters** (Figs. 1045 and 1046).—These are situated at the base of the trigone, being distant from each other about two inches when the bladder is moderately distended. Each orifice is about an inch and a half from the base of the prostate and the commencement of the urethra in the moderately distended bladder.

The **Vesical Trigone** or the **Trigonum Vesicae** (Fig. 1045) is a triangular smooth surface, with the apex directed forward, situated at the base of the bladder, immediately behind the urethral orifice. It is paler in color than the rest of the
interior, and never presents any rugae, even in the collapsed condition of the organ, owing to the intimate adhesion of its mucous membrane to the subjacent tissue. It is bounded at each posterior angle by the orifice of a ureter, and in front by the orifice of the urethra. Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, particularly prominent in old persons, called the **uvula vesicae**. It is formed by a thickening of the submucous tissue.

Stretching from one ureteral opening to the other is a smooth, slightly curved ridge, the convexity of which is toward the urethra. It is produced by transverse muscle-fibres beneath the mucous membrane. The outer prolongations of this ridge beyond the ureteral orifices are called the **ureteral folds** (*pliæ uretericae*). They are created by the ureters as they traverse the bladder wall. About the ureteral orifice are slight radial folds of mucous membrane, which are continuous with the longitudinal folds of the prostatic urethra. "In the empty bladder the ureteral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle, whose sides are about one inch in length. When the bladder is distended the distance between the openings may be increased to one and a half inches or more."^1

The muscles of the ureters were referred to on p. 1437.

The **internal urethral orifice** (*orificium urethrae internum*) is sickle-shaped and is surrounded by a circular prominence (*annulus urethralis*), which is most distinct in the male.

**Vessels and Nerves.**—The arteries (Fig. 424) supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder. The veins form a complicated plexus around the neck, sides, and base of the bladder (Fig. 474). The veins communicate below with the plexus about the prostate and terminate in the internal iliac vein.

The **lymphatics** form two plexuses, one in the muscular and another in the submucous coat. They accompany the blood-vessels. The mucous membrane of the bladder contains no lymphatics whatever (Sappey). The muscular tissue contains a few lymphatics. The subperitoneal tissues contain the usual number.

---

^1 Professor A. Francis Dixon, in Prof. D. J. Cunningham’s Text-book of Anatomy.
The collecting trunks from the anterior surface terminate in the external iliac glands. The trunks from the posterior surface terminate in the internal iliac glands, the hypogastric glands and the glands in front of the sacral promontory.

The nerves are derived from the pelvic plexus of the sympathetic and from the third and fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and to the muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distention and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended, it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region, which is perceptible to the hand as well as to percussion. In extreme distention it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this by some surgeons in performing the operation of suprapubic cystotomy. The rectum is distended by an India-rubber bag, which is introduced into this cavity empty, and is then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba, from the symphysis pubis upward, without any great risk of wounding the peritoneum. Other surgeons object to the employment of this bag, as its use is not unattended with risk, and because it causes pressure on the prostatic veins and hence produces congestion of the vessels over the bladder and a good deal of venous hemorrhage.

When distended, the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder being tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is uncovered by peritoneum.

Surgical Anatomy.—A certain defect of development in which the bladder is implicated is known under the name of extroversion of the bladder. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red, vascular protrusion, on which the openings of the urerets are visible. The penis, except the glans, is rudimentary and is eleft on its dorsal surface, exposing the floor of the urethra—a condition known as epispadias. The pelvic bones are also arrested in development (see page 220).

The bladder may be ruptured by violence applied to the abdominal wall when the viscus is distended without any injury to the bony pelvis, or it may be torn in case of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lambert sutures often saves the patient. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is also inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any persistent obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the fasciculated bladder. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the sacculated bladder, and in these little pouches phosphatic concretions may collect, forming encysted calculi. The mucous membrane is very loose and lax, except over the trigone, to allow of the distention of the viscus.

Various forms of tumors have been found springing from the wall of the bladder. The inno-
cent tumors are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous tumor, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain. Of the malignant tumors, epitheliomata are the most common, but sarcomata are occasionally found in the bladders of children.

Puncture of the bladder is performed above the pubes without wounding the peritoneum. Puncture by the rectum is not now performed, as a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been abandoned. Suprapubic cystotomy is considered above under the heading of Surface Form. This operation may be employed to permit of the removal of a calculus and is then called suprapubic lithotomy.

THE MALE URETHRA (URETHRA VIRILIS) (Figs. 1047, 1048, 1049, 1050, 1054).

The urethra in the male extends from the neck of the bladder at the internal orifice of the urethra (orificium urethrae internum) to the meatus urinarius, the external orifice of the urethra (orificium urethrae externum), at the end of the penis. The internal orifice has been described (p. 1439). The urethra presents a double curve in the flaccid state of the penis (Fig. 1054), but in the erect state of this organ it forms only a single curve, the concavity of which is directed upward. Its length varies from eight to nine inches; and it is divided into three portions, the prostatic, membranous, and spongy, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere cleft or slit, transverse, T-shaped or crescentic (Fig. 1049), with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched (Fig. 1049).

The First or Prostatic Portion (pars prostatica) (Figs. 1037, 1047, 1048, 1055, and 1056),—The first or prostatic portion is the widest and most dilatable part of the canal. It is between the internal orifice of the urethra and the superior layer of the triangular ligament and is within the pelvic cavity. It passes between the two lateral lobes of the prostate gland, from the base to the apex of the gland, lying nearer its anterior than its posterior surface. The gland seems to completely surround this portion of the urethra (Fig. 1053), but the glandular matter of the gland does not (Fig. 1051). The gland is like a buckle open in front, and the open part of the buckle is closed by the prostatic muscle. The prostatic urethra is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. Except during the passage of fluid, the canal is in a collapsed state, the anterior wall resting upon the posterior wall (Fig. 1049), and the mucous membrane exhibiting longitu-
dinal folds. When distended, the largest portion of the prostatic urethra has a diameter of about one-third of an inch. A transverse section of the canal as it lies in the prostate is horseshoe-shaped, the convexity being directed forward (Figs. 1049 and 1051). The direction of the canal is nearly vertical, there being a slight curve, which is concave forward (Figs. 1037 and 1038).

Upon the posterior wall or floor of the canal is a narrow longitudinal ridge, the crest of the urethra (crista urethralis), formed by an elevation of the mucous membrane and its subjacent tissue (Fig. 1047). This crest begins at the uvula vesicae, and passes through the prostatic portion and into the membranous portion of the urethra (Fig. 1056), and usually bifurcates at its distal end; it contains, according to Kobelt, muscular and erectile tissues. On this longitudinal ridge is an enlargement, the verumontanum or caput gallinaginis (colliculus seminalis) (Figs. 1047 and 1056). When distended, it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the floor of which is perforated by numerous apertures, the orifices of the prostatic ducts (Figs. 1047 and 1056), from the lateral lobes of the glands; the ducts of the middle lobe open behind the verumontanum. At the forepart of the verumontanum, in the middle line, is a depression, the prostatic sinus, prostatic utricle, prostatic vesicle, uterus masculinus or sinus peculiaris (utriculus prostaticus) (Figs. 1038 and 1056); and upon or within its margins are the slit-like openings of the ejaculatory ducts (ductus ejaculatorii) (Fig. 1056). The sinus peculiaris forms a cul-de-sac about a quarter of an inch in length, which runs upward and backward in the substance of the prostate behind the transverse band of prostatic tissue which joins the lateral lobes behind the posterior wall of the urethra; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the uterus masculinus, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore being homologous with the uterus and vagina in the female.

The Second, Muscular or Membranous Portion (pars membranacea) (Figs. 1047, 1048, and 1056) extends downward and forward between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meatus), and measures three-quarters of an inch along its upper, and half an inch along its lower, surface, in consequence of the bulb projecting backward.

![Fig. 1048. Proximal portions of urethra with surrounding parts. (After Testut.)](image-url)
THE MALE URETHRA

On its side the floor muscle is obliterated beneath it. Its anterior concave surface is placed about an inch below and behind the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perineum. The membranous portion of the urethra lies chiefly between the inferior and superior layers of the triangular ligament (Fig.309). The termination of this part of the urethra is overlapped by the bulb, and is in front of the triangular ligament (Fig. 306). As it pierces the inferior layer, the fibres around the opening are prolonged over the tube and fix the two structures firmly to each other. The membranous urethra is surrounded by cavernous tissue and by the Compressor urethrae muscle (m. sphincter urethrae membranaceae) (Fig.310). On the floor of the membranous urethra is the anterior extremity of the crista urethralis. Behind this part of the urethra, on each side of the middle line, are Cowper's glands (Figs. 308 and 1056). The canal enters the bulb a little in front of the posterior extremity, and the anterior wall or roof of the membranous urethra is a little longer than the posterior wall or floor. The backward projection of the bulb hangs over most of the floor of the membranous urethra (Figs. 308, 309, 1047, 1056, and 1058). When the urethra is empty the mucous membrane of the second part is thrown into longitudinal folds, which are obliterated by distention.

The Third, Penile, Pendulous, Cavernous or Spongy Portion (pars cavernosa) (Figs. 1037, 1047, 1048, and 1050) is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. It is surrounded throughout its entire course by the erectile tissue of the corpus spongiosum and glans penis. Its proximal end is fixed in position and unchangeable in direction. Its distal end is movable and changeable in direction. Commencing just below the triangular ligament it is first directed forward through the bulb; it then passes downward and forward, the turn beginning at the seat of attachment of the suspensory ligament of the penis (Fig. 1037). The direction of the third portion of the urethra is changed by alterations in the position of the penis. When the canal is closed the anterior and posterior walls are in contact (roof and floor), except in the glans

---

---

Fig. 1049.—Cross-sections of the male urethra at various distances from its free end, showing marked alterations of form. (Testut.)
penis, where the lateral walls come together. "Thus the first part of the canal when empty is represented in cross-section by a transverse slit, and the terminal part by a vertical slit" (Fig. 1049). The calibre of the spongy urethra varies in different portions of the tube. It is of larger diameter in the bulb (bulbous portion of urethra) and in the glans than between these two points. In the body of the penis the canal is of uniform size, and is about one-quarter of an inch in diameter. The fossa navicularis (fossa navicularis urethrae [Morgagni]) is an oblong dilatation of the terminal portion of the penile urethra (Figs. 1037, 1047, and 1060). In the front of the fossa navicularis there is a transverse fold of mucous membrane, the valve of Guerin (valvulae fossae navicularis). It is part of a distinct depression or pocket. The fossa navicularis opens anteriorly by the meatus urinarius.

The meatus urinarius or external orifice of the urethra (orificium urethrae externum) (Figs. 1047 and 1059) is the most contracted part of the urethra; it is a vertical slit (Fig. 1049), about three lines in length, bounded on each side by a small lip or labium.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands (Fig. 1050) situated in the submucous tissue, and named the glands of Littré (glandulae urethrales). A number of little recesses or follicles, called lacmiae (lacmiae urethrales), open into the penile urethra. Some of the glands of Littré open into the lacunae; some do not. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated in the upper surface of the fossa navicularis, about half an inch from the orifice; it is called the lacuna magna (Fig. 1060). Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The Mucous Coat.—The mucous coat forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz., Cowper's glands and the prostate gland—into the vasa deferentia and the seminal vesicles through the ejaculatory ducts. The mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it near the orifice, and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The Glands and Crypts of the Urethral Mucous Membrane (Fig. 1049).—There is a pocket, the lacuna magna (Fig. 1060), opening to the front in the upper wall of the fossa navicularis. The fossa is bounded by the valve of Guerin (valvulae fossae navicularis). The lacunae of Morgagni are in the spongy urethra back of the valve of Guerin. The lacunae look forward. The largest of them is on the roof of the fossa navicularis, one and one-half inches from the orifice (see above). Some of the lacunae receive the secretion from the glands of Littré; others do not, because some of the glands open on the free surface. The larger lacunae are one-third of an inch deep and are placed in a longitudinal row upon the anterior wall. The smaller lacunae are in longitudinal rows at the sides of the tube. The glands of Morgagni are present throughout the urethra, except in its most anterior part. In the prostatic urethra they are arranged in rows. In the membranous urethra they are scattered irregularly. In the spongy portion they are most numerous on the anterior wall and are more plentiful on the sides than on the floor. Besides the lacunae and racemose glands, there are the opening of the prostatic glands, the ejaculatory ducts, Cowper's glands, and the opening of the sinus peculiaris.

1 Professor A. Francis Dixon, in Professor D. J. Cunningham's Text-book of Anatomy.
The Submucous Tissue.—The submucous tissue consists of a vascular erectile layer. It contains the glands of Littré, especially in the posterior part. These glands are lined with cylindrical epithelium and enter the submucous coat.

The Muscular Layer.—The muscular layer is continuous with the muscle of the prostate and bladder. It is composed of non-striated muscle arranged in an outer layer of circular fibres (stratum circulare) and an inner layer of longitudinal fibres (stratum longitudinale). It is placed external to the submucous coat. In the penile urethra there is only a thin layer of longitudinal fibres. In the membranous urethra and the prostatic urethra there are two layers of muscle, an inner thin layer of longitudinal fibres and a thicker layer of circular fibres. The longitudinal fibres, when contracted, shorten the urethra and increase its diameter. The circular fibres are in a state of tonic contraction and close the urethra. In fact, they constitute the real sphincter (Zeissl, Zuckerkandl). The so-called sphincter of the urethra, the Accelerator urinae, is a voluntary muscle and is not the real sphincter. Outside of the muscular layer of the urethra is the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will at once point to the nature of the injury.

Rupture of the urethra leads to extravasation of urine. In rupture back of the superior layer of the triangular ligament the urine usually follows the rectum and reaches the margin of the anus. Rupture between the two layers of the triangular ligament liberates urine between the two layers, where it remains until a path of exit is made by suppuration or the surgeon's knife. In rupture in front of the anterior layer of the ligament the urine passes into the scrotum and may mount up to the abdomen between the symphysis and the pubic spine, between which points the deep layer of the superficial fascia is not attached. It cannot pass to the thigh nor cross the mid-line, because the fascia is attached to the fascia lata and at the mid-line.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatation, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore may require slitting, although the introduction of the Oberlander dilator, which is expanded after introduction, renders slitting of the meatus seldom necessary in cases of chronic gonorrhoea. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotripsy and introduce that of litholapaxy. In passing a fine catheter, the point of the instrument after it has passed the lacuna magna should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunae. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal. Even in a normal urethra, and very markedly in an inflamed urethra, a bougie encounters resistance behind the bulb. This is usually supposed to be due to spasm of the Compressor urethrae muscle.

In irrigation of the urethra by gravity fluid tends to block at the same point, especially if it is thrown in suddenly or forcibly. If a reservoir is raised seven and one-half feet from the floor, and if a patient sits on a chair or lies upon a bed, fluid can be readily made to pass by hydraulic pressure from the meatus to the bladder. Spasm may temporarily prevent the inflow, but the weight of the column of fluid soon tires out the muscle and causes it to relax. Relaxation is favored by having the patient take slow, deep breaths and make efforts at urination (Valentine).

Chronic gonorrhoea is frequently kept up by persistent inflammation of the ducts and follicles in the mucous membrane. This condition is known as chronic glandular urethritis or paraurethritis. In these crypts and glands gonocoeci may remain when gonorrhoea appears to have passed away, and from time to time reinflection of the urethra may arise from such a source.

Median urethrotomy or perineal section is opening of the membranous urethra. Through such an opening the bladder can be drained and explored, and the operation is sometimes called median cystotomy.

In lateral lithotomy the knife enters the membranous urethra and strikes the groove of the staff. Its edge is then turned toward the left ischial tuberosity and is carried along the groove into the bladder, dividing the membranous urethra, the prostatic urethra, the posterior layer of the triangular ligament, the Compressor urethrae muscle, anterior fibres of the Levator ani muscle and the left lobe of the prostate gland.
THE FEMALE URINARY BLADDER.

The female bladder is situated at the anterior part of the pelvis. It is in relation, in front, with the symphysis pubis; behind, with the utero-vesical pouch of peritoneum, which separates it from the body of the uterus; its base lies in contact with the connective tissue in front of the cervix and upper part of the vagina. Laterally, it is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size. It is described in the section on the Bladder (p. 1431).

THE FEMALE URETHRA (URETHRA MULIEBRIS).

The female urethra is a narrow membranous canal, about an inch and a half in length, extending from the internal urethral orifice (orificium urethrae internum) at the neck of the bladder to the vestibule of the vagina, where it ends, being called at its termination the external orifice of the urethra or the meatus urinarius (orificium urethrae externum). The meatus is usually a vertical slit. The urethra is placed behind the symphysis pubis, embedded in the anterior wall of the vagina; and its direction is obliquely downward and forward, its course being slightly curved, the concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates both layers of the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis. Except above, the posterior wall of the urethra is firmly connected to the anterior wall of the vagina.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The Muscular Coat (tunica muscularis).—The muscular coat is continuous with that of the bladder; it extends the whole length of the tube, and consists of an internal layer of non-striated longitudinal fibres (stratum longitudinalae) and an external layer of non-striated circular fibres (stratum circulare). Superficial to the circular fibres "lies a layer of cross-striped muscle-fibres, which form a closed ring near the bladder only."

The Submucous Coat (tunica submucosa).—Internal to the muscular coat is the submucous coat, which contains a venous plexus, networks from which pass between the muscular layers and impart to these layers an erectile or spongy nature (corpus spongiosum urethrae). In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethrae muscle, as in the male.

The Mucous Coat (tunica mucosa).—The mucous coat is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, extends from the vesical trigone almost to the external orifice of the urethra. It is called the crest (crista urethralis). The outline of the urethra is stellate when collapsed, because of the formation of numerous longitudinal folds. It is lined by laminated epithelium, which becomes transitional near the bladder. Many mucous glands open into the urethra, and there are numerous lacunae. External to the external orifice, on each side, a group of mucous glands opens by a common duct, the ductus para-urethralis.

The urethra, because it is not surrounded by dense resisting structures, as in the male, admits of great dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

THE MALE ORGANS OF GENERATION.

THE PROSTATE GLAND (PROSTATA) (Figs. 1048, 1051, 1052, 1053, 1054, 1055, 1056, 1057).

The prostate gland (προστάτης, to stand before) is a structure accessory to the true generative organs and furnishes a viscid, opalescent secretion in which spermatozoids will live (W. G. Richardson). It is a pale, firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and about the commencement of the urethra in the male. The prostate appears to completely surround the first portion of the urethra (Figs. 1053 and 1057), but the glandular matter does not in reality completely surround the tube (Figs. 1051 and 1057). As Spalteholz says, it partly surrounds it as a broad clasp, open in front. This opening in the glandular tissue is closed, and a complete ring is established about the urethra by the prostatic muscle (m. prostaticus) (Figs. 1051 and 1057). This muscle below is composed of striated fibres and is continuous with the Compressor urethrae (m. sphincter urethrae membranaceae); above it is composed of non-striated muscle, and is continuous with the circular muscular fibres of the bladder which surround the internal urethral orifice and
THE MALE ORGANS OF GENERATION

constitute the Sphincter vesica (Fig. 1052). The general course of the fibres is transverse, with radiations into the gland substance. The apex of the gland for about one-quarter of an inch is completely surrounded by the muscle (Fig. 1052).

Ascending from the apex the fibres cover for a short distance only the front of the gland and are attached at the sides to the fascia (Fig. 1052). Higher up the muscle passes between the sheath and the capsule and ascends to the base of the prostate, uniting the sheath to the capsule along the mid-line in front. The prostate is placed in the pelvic cavity, behind the lower part of the symphysis pubis, and above the
The deep layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged (Fig. 1055.)

The ejaculatory ducts (Figs. 1053, 1054, and 1056) enter the prostate at the margin which separates the base from the posterior surface of the gland; they pass downward, inward, and forward through the prostate, and open into the prostatic urethra. The prostate when surrounded by its sheath resembles a chestnut in shape. When dissected out from its sheath and capsule and from the Prostatic muscle, it resembles an "open clasp" or horseshoe. The sheath of the prostate is derived from the recto-vesical fascia. It is called the prostatic fascia (fascia prostatæ), is distinct and dense, and covers the entire prostate, except at the apex and at the attachment of the base of the prostate to the neck of the bladder. The prostatic fascia is a distinct structure, though it is thin. The veins of the prostatic plexus lie in the layers of the sheath, "and are everywhere separated from the prostatic capsule proper by a layer of this sheath."\(^1\) In an enlarged prostate the sheath is thick and fibrous. It is very difficult to shell out a normal prostate from its sheath, but it is easy to shell out an enlarged prostate. Within the prostatic sheath (which, be it remembered, carries the veins) is the true or proper capsule

\[1\] J. W. Thomson Walker, in the British Medical Journal, July 9, 1904.
of the prostate. The true capsule is a continuous investment from the entrance of the urethra above to the triangular ligament below. It is thin, but firm and fibrous. It is not everywhere absolutely distinct from the sheath, but may be fused
with it here and there, and many bands of fibres run from the sheath to the capsule. The capsule is continuous with the stroma of the gland and cannot be stripped off as can the kidney capsule. Any attempt to strip off the capsule tears away fragments of gland. The capsule is composed of fibrous tissue and unstriated muscle-fibres. From its deep surface the capsule is continuous with the stroma of the prostate (W. G. Richardson). Sir Henry Thompson, half a century ago, pointed out the distinction between true capsule and sheath, and suggested these names. The prostate is divided for study into a base, apex, posterior surface, anterior surface, and lateral surfaces.

The Base (basis prostaticae).—The base is directed upward, and is situated immediately below the base of the bladder. It is in contact with and supports the base of the bladder. The external longitudinal muscular layer of the bladder is attached to the posterior portion of the base of the prostate, and some of the fibres reach and adhere to the true capsule. The anterior portion of the base is called the isthmus (isthmus prostaticae) (Fig. 1053).

The Apex (apex prostaticae).—The apex is directed downward and rests upon the deep layer of the triangular ligament. The apex is fixed, except for the slight mobility of the triangular ligament; the rest of the gland is somewhat movable.

Surfaces.—The Posterior Surface (facies posterior).—The posterior surface is flattened, marked by a slight longitudinal furrow, and rests on the second part of the rectum, and is distant about one inch and a half from the anus. At the upper and posterior border of the gland are the seminal vesicles. Their direction is downward and inward; in fact, almost transverse.

The Anterior Surface (facies anterior).—The anterior surface is convex, and placed about three-fourths of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the pubo-prostatic ligament. It is shorter than the posterior surface.

The Lateral Surfaces.—The lateral surfaces are prominent, and are covered by the anterior portions of the Levatores ani muscles, which are, however, separated from the gland by a plexus of veins.

The prostate measures about an inch and a half transversely at the base, an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in position by the anterior ligaments of the bladder (ligamenta puboprostatica); by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backward from the os pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the Levator prostaticae.

The prostate consists of two lateral lobes and a middle lobe.

The Lateral Lobes (lobus dexter et sinister).—The two lateral lobes are of equal size, separated by a deep notch above, and by a furrow upon the anterior and posterior surfaces of the gland, which indicates the bilobed condition of the organ in some animals. At the upper and posterior portion of the prostate the two lobes are united by two bands of gland-tissue. One of these bands is in front of the ejaculatory ducts, the other is below them. “The upper limit of the gland is thus in the form of a horseshoe, open in front.”12 Below the level of the prostatic ducts the prostate and urethra are in relation, but are not closely connected. Above this level the connection is intimate (J. W. Thomson Walker).

The So-called Middle Lobe (lobus medius).—The middle lobe is not in reality a lobe, and the name is usually employed to describe an enlargement of the region of the prostate on the posterior portion of the urethra in front of the ejaculatory ducts. The so-called third or middle lobe is an abnormal condition. It is due to enlargement of the transverse band of prostatic tissue which joins the lateral lobes beneath the

1 W. G. Richardson on the Development and Anatomy of the Prostate Gland.
base of the bladder, behind the posterior wall of the urethra and in front of the ejaculatory ducts. This mass of tissue is beneath the uvula vesicae. Walker points out that frequently nodules of enlarged prostate protrude into the bladder, being covered only by bladder mucous membrane. This is accomplished by the enlarging prostate forcing its way through the lumen of the vesical sphincter and dilating it, and separating and passing between the strands of the internal longitudinal muscle of the bladder. "The so-called middle lobe is formed by the protrusion of a nodule between the two bands of muscle which pass into the trigone from the ureters, and unite on the posterior wall of the prostatic urethra."

The urethra passes forward between the lateral lobes of the prostate. The prostate is perforated by the ejaculatory ducts. The urethra usually lies on the level of the junction of the anterior and middle thirds of a lateral lobe. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

**Structure** (Fig. 1057).—As previously stated (p. 1449), the prostate is surrounded by a sheath from the recto-vesical fascia, and possesses also a true capsule.

The glands of the prostate are of the branched tubular variety and number forty or fifty. Many of the ducts join and form from fifteen to twenty-five smaller ducts, which empty into the prostatic urethra, to the sides of the verumontanum (Fig. 1056). The ducts and glands are lined with cubical epithelium. The prostatic secretion or prostatic fluid (succus prostaticus) is a viscid, opalescent, serous secretion, alkaline in reaction, containing a ferment, but no mucus. The substance of the prostate is of a pale, reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland ramify. The true capsule is continuous with the stroma. The stroma lies between the glandular substance and strands of stroma pass in convergent lines toward the prostatic urethra, especially toward the dorsum of the urethra. These strands or septa divide the prostate into small irregular subdivisions called lobules. Next to the urethra, the stroma forms a thick layer. As age advances the interstitial tissue of the prostate increases and the glandular substance shrinks.

**Vessels and Nerves.**—The arteries supplying the prostate are derived from the internal pudic, inferior vesical, and middle haemorrhoidal. Branches of the vessels enter the gland in the septa between the lobules and send off minute branches to the lobules (Walker). The veins form a plexus around the sides and base of the gland between layers of the fascial sheath; they receive in front the dorsal vein of the penis, and terminate in the internal iliac vein. The lymphatics of the prostate begin as networks about the acini of the gland, pass to beneath the capsule, and form another network, and from this peripheral network collecting trunks arise. Several trunks pass from the posterior portion of the gland. One trunk passes to the external iliac glands, one to the internal iliac glands, and several end in the lateral sacral glands, and the glands of the sacral promontory. An anterior trunk is joined by lymphatics from the membranous urethra and prostatic urethra and passes to a gland on the internal pudic artery. The nerves are derived from the hypogastric plexus.

**Surgical Anatomy.**—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys,

---

2 Poirier and Charpy. Human Anatomy.
learn the position, as well as the size and weight, of a calculus in the bladder. In the operation for the removal of a calculus, if, as is not unfrequently the case, the stone should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhoea, or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of an abscess, and also explains the great pain which is present in acute inflammation. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perineum. In advanced life the prostate often becomes considerably enlarged, and may project into the bladder so as to impede the passage of the urine. According to Dr. Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. The prostate may be enlarged by the growth of innocent tumors, adenomata, fibromata, myomata, and myofiromata. The entire gland may be hypertrophied. A tumor may be encapsulated, but often is surrounded by an area of hyperplasia of prostatic tissues, and usually the area of hyperplasia is much more extensive than the tumor. A tumor may be beneath the mucous membrane, deep in the gland, or beneath the sheath. The growth called the third lobe is submucous. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the nodule forms the so-called middle lobe, and even a small enlargement of this character may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the prostate. In consequence of the enlargement of the prostate a pouch is formed at the base of the bladder behind the projection, in which urine collects and cannot entirely be expelled. The urine becomes decomposed and ammoniacal, and leads to cystitis. If the prostate enlarges the urethra is lengthened, often dilated, altered in shape, or distorted.

The relation of the enlarged prostate to the neck of the bladder is greatly altered from the relation of the normal prostate. Normally, it is extravesical; when enlarged it may encase "the neck of the bladder in a cuff-like manner, extending several inches upward on its wall," and often it protrudes "into the vesical cavity, carrying on its surface the mucosa vesicae." In many cases of prostatic enlargement the gland should be removed (prostatectomy). One method is enucleation through a suprapubic incision; another method is enucleation through a perineal incision; another method is carried out by both incisions (the combined method).

The Bottini operation is prostatotomy, effected by a special instrument for the purpose of cauterizing the gland and thus causing shrinking.

In elderly individuals the gland tubules may form round, indurated, and sometimes calcified masses, about 1 mm. in diameter, and called prostatic stones.

**COWPER’S GLANDS (GLANDULAE BULBO-URETHRALES)** (Figs. 1056, 1063).

Cowper's glands are two small, rounded, and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the forepart of the membranous portion of the urethra, between the two layers of the triangular ligament. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethrae muscle. Their existence is said to be constant; they gradually diminish in size as age advances.

**Structure.**—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct (ductus excretorius). The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

**THE PENIS** (Figs. 1058, 1059, 1060, 1061, 1062, 1063).

The penis is a long body of prismatic shape placed below and in front of the symphysis pubis. It surrounds the greatest length of the urethra. It consists of a root, body, and extremity or glans penis. The root and the posterior portion

1 John B. Murphy, in the Journal of the American Medical Association, May 28, 1904.
of the body lie beneath the scrotum and the integument of the perineum (Fig. 1054), and are firmly fixed to the triangular ligament, the pubic bones, and the symphysis; hence this portion of the organ is called the fixed portion (pars fixa) (Fig. 309). The balance of the organ is free

and movable (Fig. 1054), and is called the mobile portion (pars mobilis). When the penis is relaxed there is an angle between the fixed and mobile portions; when the penis is erect, the angle disappears.

The Root (radix penis).—The root is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the crura (Figs. 1058, 1062, and 1063), and to the front of the symphysis pubis by the suspensory ligament (Fig. 1061), a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the root of the penis.

The extremity, acorn or glans penis (Figs. 1059 and 1060) presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the external orifice of the urethra or the meatus urinarius (orificium urethrae externum). The base of the glans forms a rounded projecting border, the corona glandis, and behind the corona is a deep constriction, the cervix or neck (collum glandis). Upon both the corona and neck numerous small sebaceous glands are found, the glandulae Tysonii odoriferae. They secrete a sebaceous matter of very peculiar odor, which probably contains caseine and becomes easily decomposed.

1 Stieda (Comptes-rendus du XII. Congrès International de Médecine, Moscow, 1897) asserts that Tyson's glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillae.—Ed. of 15th English edition.
The Body of the Penis (*corpus penis*).—The body of the penis is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect it has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the **dorsum penis**. The lower surface of the body of the penis is called the **urethral surface** (*facies urethralis*). The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and for the absence of adipose tissue. At the root of the penis the integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the **prepuce** (*praeputium*) (Fig. 1059). The internal layer of the prepuce is attached behind to the **cervix or neck** (Fig. 1059), and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The integument covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillae.

---

**Fig. 1061.**—The suspensory ligament. (Poirier and Charpy.)

At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphe, where it is continuous with the prepuce; this fold is termed the **fraenum** (*frenulum praeputi*). The skin of the penis covers the mobile parts of the organ. It is thin, extremely elastic, and contains very few hairs. Beneath the skin of the penis is the **dartos layer** (Figs. 1061 and 1068), continuous with the scrotal dartos, containing chiefly non-striated muscular fibres arranged longitudinally. It passes forward to the orifice of the prepuce, and then turns backward, growing thinner and thinner, and finally disappearing at the cervix. Beneath the dartos and extending forward to the orifice of the prepuce is a sheath of **areolar tissue**. It is a lax sheath rich in elastic tissue and containing almost no fat. The superficial vessels and nerves are in the areolar sheath. Beneath the areolar sheath of the penis, from the corona to the root, is the **fascia of the penis** (*fascia penis*) (Fig. 1068). It covers the organ from the root to the corona, and also covers the dorsal artery, veins, and nerves. It is continuous behind with the superficial perineal fascia and suspensory ligament. It is composed chiefly of elastic tissue.

**Structure of the Penis.**—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the **corpora**
cavernosa, are placed side by side along the upper part of the organ; the third, or corpus spongiosum, encloses the urethra and is placed below.

The Two Corpora Cavernosa (corpora cavernosa penis) (Figs. 1062 and 1063).—The two corpora cavernosa form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the crura penis, which are two strong tapering fibrous processes or roots firmly connected to the rami of the os pubis and ischium (Figs. 1058, 1062, and 1063). Each crus commences by a...
blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the bulb of the corpus cavernosum. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis (Figs. 1060 and 1062). A median groove on the upper surface lodges the dorsal arteries, nerves, and veins of the penis (Figs. 1066, 1067, and 1068), and the groove on the under surface receives the corpus spongiosum (Fig. 1062). The root of the penis is connected to the symphysis pubis by the suspensory ligament.

Structure (Fig. 1068).—Each corpus cavernosum is composed of erectile tissue. The erectile tissue is surrounded by a strong fibrous envelope, the tunica albuginea, corporum cavernosum, consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, circular in direction, and being proper to each corpus cavernosum. The internal circular fibres of the two corpora cavernosa form, by their junction in the mesial plane, an incomplete partition or septum, the septum penis, between the two bodies.

The septum between the two corpora cavernosa is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, septum pectiniforme. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. The fibrous investment of the corpora cavernosa is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of each crus in all directions, subdividing it into a number of separate compart-
ments, and giving the entire structure a spongy appearance. These bands and cords are called **trabeculae corporum cavernosum**, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are continued numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger around the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are called **cavernous spaces** and are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins (Fig. 1065).

The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue the areolar spaces of which freely communicate with each other and are filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the **arteries of the corpora cavernosa** and branches from the **dorsal artery of the penis**, which perforate the fibrous capsule, along the upper surface, especially near the forepart of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces (Fig. 1065); others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller **helicine arteries** (*arteriae helicincae*). They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa.

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the **deep dorsal vein**; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind around the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the **prostatic plexus**.

**The Corpus Spongiosum** (*corpus cavernosum urethrae*) (Figs. 1060, 1062, and 1063).—The corpus spongiosum encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa penis. It commences posteriorly below the superficial layer of the triangular ligament of the urethra, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the **bulb of the urethra** (*bulbus urethrae*), and terminates anteriorly in another expansion, the **glans penis** (Figs. 1059, 1060, 1062, and 1063), which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

**The Bulb of the Urethra** (Figs. 1058, 1062, and 1063) varies in size in different subjects; it receives a fibrous investment from the superficial layer of the triangular ligament, and is surrounded by the Accelerator urinae muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward around the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two **lobes** (*hemisphaeria bulbi urethrae*), being marked externally by a linear raphé, whilst internally there projects, for a short distance, a thin **fibrous median septum** (*septum bulbi urethrae*), which is more distinct in early life.
Structure.—The corpus spongiosum consists of a strong fibrous envelope enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora cavernosa of the penis. The trabeculae are more delicate, more nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

Ligaments of the Penis.—The suspensory ligament (ligamentum suspensorium penis) (Fig. 1061) is firm and fibrous. It passes from the front of the symphysis pubis to the tunica albuginea of the corpora cavernosa. The ligamentum fundiforme penis (Fig. 1058), formerly called the suspensory ligament, arises from the linea alba, sheath of the rectus, superficial fascia, and symphysis pubis, and surrounds the penis in a loop, being attached more distalward than is the suspensory ligament, and usually passes into the scrotum. It is composed of elastic tissue.

Vessels and Nerves of the Penis.—The arteries (Fig. 1066) of the penis come from branches of the internal pudic artery. The deep arteries of the penis give the chief supply to the erectile tissue of the corpora cavernosa, and the dorsal artery also sends branches to it; the artery of the bulb (p. 691) supplies the erectile tissue of the corpus spongiosum. The chief blood-supply of the glans is from the dorsal artery (p. 692). In the trabeculae the arteries are very small and often twisted. The twisted vessels are called helicine arteries. The small arteries open directly into the venous spaces. The veins of the penis empty directly into
the prostatic plexus or into the deep dorsal vein, which empties into the prostatic plexus. On each side of the deep dorsal vein is a dorsal artery and external to each dorsal artery is a dorsal nerve (Fig. 1068). The superficial dorsal vein (Figs. 1067 and 1068), receiving small veins from the prepuce, passes back beneath the skin, reaches the symphysis and divides into two branches, each of which passes to the corresponding superficial external pudic vein.

The lymphatics of this region have been studied carefully by Poirier, Cunéo, and Delamare,1 which book I have freely used.

The lymphatics of the skin of the penis and prepuce are continuous (Fig. 501). Those on the internal surface of the prepuce are continuous with those of the glans. The trunks of the cutaneous lymphatics anastomose with each other, ascend by the dorsal vein, and terminate in the inguinal glands. The trunks from the glans converge toward the frenum; they then ascend to the median part of the corona, and the vessels of the two sides unite. Several collectors ascend on the dorsum to the inguinal and femoral glands.

The superior wall of the anterior portion of the urethra is drained by the lymphatic trunks from the glans. From the rest of the penile urethra the lymphatics unite with the trunks from the penis, and most of them terminate in the same way, although one of them passes between the recti muscles and terminates in the deeper external iliac glands or in the "internal retro-crural gland."2

The trunks from the bulb and membranous urethra terminate in the external iliac glands, the "internal retro-crural gland," and the glands along the internal pudic artery (Poirier, Cunéo, and Delamare). The trunks from the prostatic urethra join the trunks from the prostate gland.

The nerves are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bulb.

Surgical Anatomy.—It is occasionally necessary to remove a penis for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the ossa pubis and ischia. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue around the root of the penis, and carried down the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the spongy portion of the urethra below the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perineum. The remainder of the wound is to be brought together, free drainage being provided for.

---

1 Translated and edited by Cecil H. Leaf.
THE TESTICLES (TESTES) AND THEIR COVERINGS (Figs. 1071, 1072).

The testicles are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of foetal life the testes are contained in the abdominal cavity, behind the peritoneum, but they subsequently descend into the scrotum.

DESCENT OF THE TESTIS (DESCENDUS TESTIS).

Each testis at an early period of foetal life is placed at the back part of the abdominal cavity, behind the peritoneum, in front and a little below the kidney. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the gubernaculum testis, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring to the epididymis and body of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the mesorchium, which also encloses the gubernaculum and forms two folds—one above the testicle, and the other below it. The one above the testicle is the plica vascularis, and contains ultimately the spermatic vessels; the one below, the plica gubernatrix, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the processus vaginalis, which now lies in the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum constituting the processus vaginalis projects itself downward into the inguinal canal, forming a gradually elongating depression or cul-de-sac, which eventually reaches the bottom of the scrotum. This cul-de-sac is now invaginated by the testicle, as the body of the foetus grows, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the
THE MALE ORGANS OF GENERATION

scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal, and eventually into the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the tunica vaginalis.1

Mr. Jacobson2 says that the attachments of the gubernaculum above are to the vas, the epididymis, and afterward to the testicle. The lower attachments of the gubernaculum, some of which are temporary, are the abdominal wall, pubes and root of the scrotum, Scarpa's triangle, perineum and scrotum. The remains of the scrotal fibres constitute a so-called ligament of the scrotum or the mesorchium, which causes adhesion between the testicle and skin (Fig. 1070).

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male; it is called the canal of Nuck.

Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed, or it may be fully developed and the vas deferens may be undeveloped in whole or in part; or, again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent (cryptorchismus) or it may descend into some abnormal position (ectopia testis). Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position; it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. Ectopia testis is due to the absence, overdevelopment or malposition of some portion of the gubernaculum. There is still a third class of cases of abnormality in the position of the testicle, where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testicle is inverted; that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hematocèle, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be reversed. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.

THE COVERINGS OF THE TESTICLE (Fig. 1073).

The coverings of the testicle are the following:

Skin } Scrotum.
Dartos } Intercolumnar or External spermatic fascia.
Cremasteric fascia.
Infundibuliform or Fascia propria (Internal spermatic fascia).
Tunica vaginalis.

The Testicular Bag or Scrotum (Figs. 1071 and 1072).—The testicular bag or scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided on its surface into two lateral portions by a median line or

---

1 The obliteration of the process of peritoneum which accompanies the cord, and is hence called the funicular process, is often incomplete. See section on Inguinal Hernia.
2 Diseases of the Male Organs of Generation.
The coverings of the testicle

raphe (raphe scroti), which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is usually longer than the right, and corresponds with the usual greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances: thus under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes. The wrinkles in the scrotum are called rugae.

The scrotum consists of two layers, the integument and the dartos.

The Integument.—The integument is very thin, of a brownish color, and generally thrown into folds or rugae. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

The Dartos (tunica dartos) (Figs. 1064 and 1071).—The dartos is a thin layer of loose tissue, endowed with contractility; it forms the proper tunic of the scrotum, is continuous around the base of the scrotum, with the two layers of the superficial fascia of the groin and perineum, and sends inward a distinct septum, the septum of the scrotum (septum scroti) (Fig. 1071), which divides it into two cavities for the two testes, the septum extending between the raphe and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the
subjeacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstriped muscular fibre, but no fat. Its contractibility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The **Intercolumnar or Spermatic Fascia** (Fig. 1071).—The intercolumnar fascia is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testis in the foetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **Cremasteric Fascia** (*fascia cremasterica*) (Figs. 1071 and 1072).—The cremasteric fascia consists of scattered bundles of muscular fibres, the **Cremaster muscle** (*m. cremaster*) (Figs. 1071 and 1072) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are continuous with the lower border of the Internal oblique muscle.
The Infundibuliform Fascia (tunica vaginalis communis [testis et unicii spermatici]) (Figs. 1071 and 1071).—The infundibuliform fascia is a thin membranous layer, which loosely invests the surface of the cord. It is a continuation downward of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior parts of the testicle. This connective tissue is continuous above with the subserous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath
it, are known collectively as the *fascia propria*. The infundibuliform fascia completely encloses the testicle and epididymis and is fused with the parietal lamina of the tunica vaginalis propria testis.

**The Tunica Vaginalis (tunica vaginalis propria testis).**—The tunica vaginalis is described with the testis (p. 1469.)

**Vessels and Nerves.**—The arteries supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the deep epigastric. The veins follow the course of the corresponding arteries. The lymphatics terminate in the inguinal glands. The nerves are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

---

**THE SPERMATIC CORD (Funiculus Spermaticus)**

(Figs. 1071, 1072, 1075, 1076).

The spermatic cord extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique muscle and upon the fascia transversalis; but nearer the pubes it rests upon Poupart’s ligament, having the aponeurosis of the External oblique in front of it and the conjointed tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is usually rather longer than the right, consequently the left testis generally hangs somewhat lower than its fellow.

**Structure.**—The spermatic cord contains the spermatic duct, the deferential artery and veins, the spermatic artery, the pampiniform plexus of veins, the spermatic plexus, and the deferential plexus of the sympathetic nerve, lymphatics, and the cord-like remnant of the funicular process of peritoneum called the *ligament*.
of Cloquet (Fig. 1075). All the above structures are held together by connective tissue. These structures are ensheathed by the **infundibuliform process of the transversalis fascia** (tunica vaginalis communis [testis et funiculi spermatici]) (Fig. 1075 and p. 1064). This fascia is thin above and thicker below, and encloses the testicle and epididymis, as well as the cord, being firmly adherent to the parietal layer of the **vaginal tunic of the testicle** and with the posterior portion of the testicle and epididymis. Upon this fascia are the fibres of the Cremaster muscle, which spring from the internal oblique, and in this fascia are the cremasteric artery, the genital branch of the genito-crural nerve, and external spermatic veins. This fascia is surrounded by the **intercolumnar or spermatic fascia** (fascia cremasterica [Cooperi]), which is distinct above, but not below.

**Vessels and Nerves of the Spermatic Cord.**—The arteries (Figs. 1074 and 1080) of the cord are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastric.

The **spermatic artery** (a. spermatica interna) arises from the abdominal aorta below the renal artery, descends by the Psoas muscle, crosses the ureter and external iliac vessels, meets the vas deferens at the internal abdominal ring, escapes from the abdomen at the internal or deep abdominal ring, and lying in front of the vas deferens accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which, the **epididymal branches**, accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens and the cremasteric artery; others, the **glandular branches**, pierce the back of the tunica albuginea and supply the substance of the testis.

The **artery of the vas deferens**, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery and the cremasteric artery near the testis.
The cremasteric artery (a. spermatica externa) is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic and deferential arteries.

The spermatic veins (Figs. 1074, 1075, 1076, and 1077) emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus, the pampiniform plexus (plexus pampiniformis), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or super-

Fig. 1077.—Spermatic veins. (Testut.)

ficial abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the renal vein at a right angle.

The lymphatic vessels of the scrotum terminate in the superficial inguinal glands. The lymphatics of the testicle join the lymphatics of the epididymis and of the visceral layer of the vaginal tunic of the testicle, and ascend in the spermatic cord. They reach the lumbar region along the spermatic blood-vessels and terminate in the juxta-aorta glands, and sometimes in the glands in front of the aorta. The lymphatics of the seminal duct pass to the external iliac glands.
The nerves are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

The Ligament of the Scrotum.—See Fig. 1070 and p. 1462.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum, and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distention, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of edema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of epithelioma; this is no doubt due to the rugae on its surface, which favor the lodgement of dirt, and this, causing irritation, is the exciting cause of the disease. Cancer was especially common in chimney-sweeps from the lodgement of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

THE TESTICLES (TESTES) (Figs. 1069, 1071, 1072, 1078, 1079).

The testicles are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the upper extremity (extremitas superior) being directed forward and a little outward, the lower extremity (extremitas inferior), backward and a little inward; the anterior convex border (margo anterior) looks forward and downward; the posterior or straight border (margo posterior), to which the cord is attached, backward and upward.

The anterior border and lateral surfaces (facies lateralis et facies medialis), as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the epididymis (οίδοθήκα, testis) (Figs. 1078 and 1079). The curve of the epididymis is convex outward and backward. It consists of a central portion or body (corpus epididymidis); an upper enlarged extremity, the head or globus major (caput epididymidis); and a lower pointed extremity, the tail or globus minor (cauda epididymidis). The globus major is directed inward and is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The globus minor bends suddenly and passes into the seminal duct, the direction of which is upward and backward. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border, and between the body and the testicle is a pouch or cul-de-sac, named the digital fossa (sinus epididymidis). Above this fossa is a fold of the tunica vaginalis, which is called the ligamentum epididymidis superior, and below it is another fold, the ligamentum epididymidis inferior. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, is a small body. It is oblong in shape and has a broad base. Attached to the globus major of the epididymis is another small body, which is pear-shaped and has a stalk. These bodies are
believed to be the remains of the upper extremity of the Müllerian duct, and are termed the **hydatids of Morgagni**; some observers, however, regard the stalked hydatid as being a rudiment of the pronephros. The body with a broad base is the **non-pedunculated hydatid** \((\textit{appendix testis [Morgagnii]}\) (Figs. 1071 and 1078); the pear-shaped body is the **pedunculated hydatid** \((\textit{appendix epididymidis})\). When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

**Size and Weight.**—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

**The Tunics of the Testicle.**—The testis is invested by three tunicsthe **tunica vaginalis**, **tunica albuginea**, and **tunica vasculosa**.

**The Proper Sheath of the Testicle** or the **Tunica Vaginalis** \((\textit{tunica vaginalis propria testis})\) (Figs. 1069, 1071, 1072, 1073, and 1080) is the serous covering of the testicle and epididymis. It is a pouch of serous membrane, derived from the peritoneum \((\textit{processus vaginalis peritonaei})\) during the descent of the testis in the fetus from the abdomen into the scrotum. After its descent that portion of the pouch which
extends from the internal ring to near the upper part of the gland, the **funicular process**, becomes obliterated, the lower portion remaining as a shut sac (**tunica vaginalis propria testis**), which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

- The **Visceral Portion** (*lamina visceralis*) of the tunica vaginalis propria covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the infundibuliform process of the transversalis fascia, and between the tunica and the fascia is a layer of unstriated muscle fibres, the **Internal cremaster muscle** (Fig. 1073).

- The **Parietal Portion** (*lamina parietalis*) of the tunica vaginalis propria is the reflected portion. It is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the **cavity of the tunica vaginalis** and contains a small amount of serous fluid.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread, the **ligament of Cloquet** (*rudimentum processus vaginalis*) (Fig. 1075), lying in the loose areolar tissue around the spermatic **cord**; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia; or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.1

- The **Tunica Albuginea** (Figs. 1073, 1079, and 1080).—The tunica albuginea is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interface in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testicle, and along its posterior border, where the spermatic vessels enter the gland. This membrane surrounds the glandular structure of the testicle, and at its posterior border forms a projection, triangular in shape and cellular in structure, which is reflected into the interior of the gland, forming an incomplete vertical septum, called the **mediastinum testis**.

- The **Mediastinum Testis** (*corpus Highmori*) (Figs. 1073, 1079, and 1080) extends from the upper, nearly to the lower, extremity of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa, called the **trabeculae** (*septula testis*) (Fig. 1080), are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. This scaffolding of connective tissue divides the **parenchyma** (*parenchyma testis*) of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the blood-vessels, lymphatics, and ducts of the testis in their passage to and from the substance of the gland, and contains numerous fine canals, into which open the very small tubules of the proper substance of the testicle.

---

1 It is recorded that in the post-mortem examination of Sir Astley Cooper a minute funicular canal was found on each side of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (Lancet, 1824, vol. ii. p. 116.).—Ed. of 15th English edition.
The Tunica Vasculosa (Fig. 1073).—The tunica vasculosa is the vascular layer of the testis, and consists of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure of the Testicle and Epididymis (Fig. 1080).—The glandular structure of the testis consists of numerous lobules (lobuli testis). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base of each being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, which Anastomose with each other, the tubuli seminiferi contorti. The contorted tubes unite at the apex of the lobules and form the straight tubes (tubuli seminiferi recti). The straight tubes pass into the mediastinum testis and form the network known as the rete testis of Haller (Fig. 1080). The rete testis is lined with flattened epithelium. The tubes are lined with columnar ciliated epithelium. The efferent ducts (ducti efferentes testis) (Fig. 1080), about twelve to fifteen in number, arise from the rete. The contorted tubes may be separately unrolled by careful dissection under water, and may be seen to commence either by free caecal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300 and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from $\frac{1}{25}$ to $\frac{1}{10}$ of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep-yellow tinge from containing much fatty matter. Each tube consists of a basement layer, formed of epithelioid cells united edge to edge, outside of which are other layers of flattened cells arranged in interrupted laminae, which give to the tube an appearance of striation in cross-section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups. Among these cells may be seen the spermatozooids in different stages of development. 1. Lining the basement-membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the lining cells or spermatogonia. The nucleus of some of them may be seen to be in the process of indirect division (karyokinesis), and in consequence of this daughter cells are formed, which constitute the second zone. 2. Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three layers; these are the intermediate cells or spermatocytes. Most of these cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the spermatoblasts or spermatids. 3. The third layer of cells therefore consists of the spermatoblasts or spermatids, and each of these, without further subdivision, becomes a spermatozoid. They are ill-defined granular masses of protoplasm, of an elongated form, with a nucleus which becomes the head of the future spermatozoid. In addition to these three layers of cells others are seen, which are termed the supporting cells, or cells of Sertoli. They are elongated and columnar, and project inward from the basement-membrane toward the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermatozooids proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear part of the spermatozoid, which is partly embedded in the supporting cell, is differentiated to form the head of the spermatozoid, while the cell protoplasm becomes lengthened out to
form the middle piece and tail, the latter projecting into the lumen of the tube. Ultimately the heads are separated and the spermatozoids are set free.

Spermatogenesis.—The stages in the development of the spermatozoids are as follows: The spermatogonia become enlarged to form the spermatocytes, and each spermatocyte subdivides into two cells, and each of these again divides into two spermatids or young spermatozoids, so that the spermatocyte gives origin to four spermatozoids.

The process of spermatogenesis bears a close relation to that of maturation of the ovum. The spermatocyte is equivalent to the immature ovum. It undergoes subdivision, and ultimately gives origin to four spermatozoids, each of which contains, therefore, only one-fourth of the chromatin elements of the nucleus of the spermatocyte. In the process of maturation of the ovum its nucleus divides, one-half being extended as the first polar body. The remaining half of the nucleus again subdivides, one-half being extended as the second polar body. The portion of the nucleus which is retained to form the female pronucleus of the now matured ovum contains, therefore, only one-fourth of the chromatin elements of the original nucleus, and thus the spermatozoid and the matured ovum, so far as their nuclear elements are concerned, may be regarded as of the same morphological value.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

The Aberrant Ducts of the Epididymis (ductuli aberrantes) are tortuous and end in blind extremities. The superior aberrant duct (ductus aberrans superior) is in the globus major and joins the rete testis. The inferior aberrant duct (ductus aberrans inferior) (Fig. 1080) is in the tail of the epididymis, and takes origin from the duct of the epididymis or the seminal duct. It is a persistent canal of the Wolffian body. It extends up the cord for two or three inches and terminates by a blind extremity, which is occasionally bifurcated. It may be as much as fourteen inches in length. Its structure is similar to that of the seminal duct.

The Seminal Duct or Vas Deferens (ductus deferens) (Figs. 1074, 1075, 1076, 1080, 1081, and 1118).—The seminal duct or vas deferens, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves around the outer side of the internal epigastric artery and vein, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the seminal vesicle. Behind the bladder it becomes enlarged and sacculated, forming the ampulla (ampulla ductus deferentis) (Fig. 1081), and then, becoming narrowed at the base of the prostate, unites with the duct of the seminal vesicle to form the ejaculatory duct (Fig. 1082). From the internal abdominal ring to the middle of the ampulla the seminal duct is beneath the peritoneum. The vas deferens offers a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external or areolar coat (tunica adventitia). 2. A muscular coat (tunica muscularis), which in the greater part of the tube consists of two layers of unstriped muscular fibre: an inner layer of thin longitudinal fibres (stratum internum) existing only at the beginning,
a thick layer of circular fibres (stratum medium), and a thick external layer of longitudinal fibres (stratum externum). 3. An internal or mucous coat (tunica mucosa), which is pale, and arranged in longitudinal folds; its epithelial cells are of the columnar variety.

Organ of Giraldes (paradidymis).—This term is applied to a small body of rounded shape in the lower end of the spermatic cord, in front of the blood-vessels. It consists of a small collection of minute vesicles and a small collection of convoluted tubules. These tubes are lined with columnar ciliated epithelium, and probably represents the remains of a part of the Wolffian body.

Surgical Anatomy.—Abnormalities in the descent and position of the testicle have been discussed (p. 1462). The testicle may require removal for malignant disease, tuberculous disease, cystic disease, in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicles. The operation of double castration has also been, during the last few years, performed for enlargement of the prostate gland; for it has been found that removal of the testicles is followed by very rapid and often considerable diminution in the size of the prostate. The operation is, however, one of severity, and is frequently followed by death in these cases, performed, as it necessarily is, in old men. Reginald Harrison has proposed to substitute for it excision of a portion of each vas deferens (vasectomy). The operation of castration is a comparatively simple one. An incision is made into the cavity of the tunica vaginalis from the external ring to the bottom of the scrotum. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

A collection of serous fluid in the sac of the vaginal tunic of the testicle is known as an ordinary or testicular hydrocele. In congenital hydrocele a communication remains between the tunica vaginalis testis and the peritoneal cavity. This communication should have closed during development. In infantile hydrocele the tunica vaginalis and part of the funicular process are distended with fluid, but the funicular process is closed above and the cavity of the hydrocele does not communicate with the peritoneal cavity. In encysted hydrocele of the cord the funicular process is closed above and below, but between these points is not obliterated. In infantile hydrocele the funicular process is closed below and open above. Congenital hydrocele can usually be cured by the application of a truss. This obliterates the upper end of the funicular process, and the obliteration once begun may proceed to completion. If it does not, the condition has become an infantile hydrocele. An infantile hydrocele can usually be cured by multiple punctures or tapping. The same is true of encysted hydrocele of the cord. In hydrocele of the funicular process wear a truss for a time and then tap. In ordinary testicular hydrocele incise and pack, or incise and suture, the cut edge of the parietal layer of the tunic to the skin, or extirpate the parietal layer of the tunic. A successful method is that of Longuet. He makes an incision, pulls out the testicle, and allows all the coats except the skin to fall behind and make a sheath for the cord. These coats are held behind by one catgut suture. A bed is made for the testicle beneath the skin toward the septum of the scrotum. The testicle is rotated on its long axis and placed in the bed, and the skin is sutured above it. This operation is known as extraneous transposition. If a portion of bowel enters an open vaginal process the condition is congenital hernia.

In infantile hernia the funicular process is closed above but not below, and the hernia descends in a special sac back of the vaginal tunic. If the hernia pushes down on the vaginal process and causes it to double on itself the condition is encysted infantile hernia.

The Semen and the Spermatozoids.—Semen consists of spermatozoids with liquids and solids. Part of the semen comes from the testicles, most of it from accessory glands—that is, from the glands of the seminal ducts, the seminal vesicles, the prostate gland, and Cowper’s glands. Semen is a viscid, whitish fluid, of alkaline reaction and characteristic odor. It contains water and about 18 per cent. of solid matter. In this solid matter are fat, cholesterol, lecithin, proteids, nuclein, xanthin, chlorides, sulphates, and phosphates of sodium and potassium. Böttcher’s crystals, which can be obtained from semen, are composed of phosphate of spermine. Spermine is a nitrogenous substance. The fluid portion of semen carries and probably nourishes the living cells known as spermatozoids.
The seminal vesicles (VESICULAE SEMINALES) (Figs. 1082, 1083).

The seminal vesicles are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal in form, the broad end being directed backward and the narrow end forward toward the prostate. It measures about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. The upper surface is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. The under surface rests upon the rectum, from which it is separated by the recto-vesical fascia. Their posterior extremities diverge from each other. Their anterior extremities are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding seminal duct to form the ejaculatory duct. Along the inner margin of each vesicle runs the enlarged and convoluted vas deferens. The inner border of the vesicle and the corresponding seminal duct form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum.

Each vesicle consists of a single tube, coiled upon itself and giving off several irregular caecal diverticula (Fig. 1082), the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a cul-de-sac; its anterior extremity becomes constricted into a narrow straight duct, the excretory duct (ductus excretorius) (Fig. 1083), which joins with the corresponding seminal duct, and forms the ejaculatory duct.

The Ejaculatory Ducts (ductus ejaculatorii) (Fig. 1083).—The ejaculatory ducts are two in number, one on each side. Each duct is formed by the junction of the duct of the seminal vesicle with the seminal duct. Each duct is about three-quarters of
an inch in length; it commences at the base of the prostate, and runs forward and downward between the middle and lateral lobes of that gland, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to or just within the margins of the sinus. The ducts diminish in size and also converge toward their termination.

Structure.—The seminal vesicles are composed of three coats: an external or areolar (tunica adventitia); a middle or muscular coat (tunica muscularis), which is thinner than in the seminal duct, and is arranged in two layers, an outer, longitudinal, and inner, circular; an internal or mucous coat (tunica mucosa), which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an outer fibrous layer, which is almost entirely lost after the entrance of the duct into the prostate; a layer of muscular fibres, consisting of an outer thin circular and an inner longitudinal layer; and the mucous membrane.

Vessels and Nerves.—The arteries supplying the vesiculae seminales are derived from the middle and inferior vesical and middle haemorrhoidal. The veins and lymphatics accompany the arteries. The lymphatics anastomose on the surface of the vesicle. The trunks from this network anastomose with the lymphatics of the bladder and prostate, and pass to the external and internal iliac glands. The nerves are derived from the pelvic plexus.

Surgical Anatomy.—The vesiculae seminales are often the seat of an extension of the disease in cases of tuberculosis of the testicle, and should always be examined through the rectum before coming to a decision with regard to castration in this affection. The vesicles have been deliberately extirpated for local tuberculosis. In gonorrhea the seminal vesicles may become acutely inflamed (acute seminal vesiculitis). Chronic seminal vesiculitis may follow the acute form or may arise insidiously during gonorrhea.
THE FEMALE ORGANS OF GENERATION.

EXTERNAL ORGANS (PARTES GENITALES EXTERNAE MULIEBRES).

THE external organs of generation in the female are: the mons Veneris, the labia majora and minora, the clitoris, the meatus urinarius, and the orifice of the vagina. The term vulva (pudendum muliebre), as generally applied, includes all of these parts.

THE MONS VENERIS (MONS PUBIS) (Figs. 1085, 1086).

The mons Veneris is the rounded eminence in front of the pubic symphysis, formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

THE LARGE LIPS OR LABIA MAJORA (LABIA MAJORA PUDENDI) (Figs. 1085, 1086, 1087).

The large lips or labia majora are two prominent longitudinal cutaneous folds extending downward from the mons Veneris to the anterior boundary of the perineum, and enclosing the common urino-sexual opening. Each labium majus (labium majus pudendi) has two surfaces, an outer, which is pigmented and
THE FEMALE ORGANS OF GENERATION

covered with strong, crisp hairs; and an inner, which is smooth and is beset with large sebaceous follicles and is continuous with the genito-urinary mucous tract; between the two there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and sweat and sebaceous glands. Between the labia majora is the pudendal slit (rima pudendi). The labia are thicker in front, where they form by their meeting the anterior commissure (commissura labiorum anterior). Posteriorly they are not really joined, but appear to become lost in the neighboring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the posterior commissure (commissura labiorum posterior), or posterior boundary of the vulval orifice. The interval between the posterior commissure and the anus, about an inch to an inch and a quarter in length, constitutes the obstetric perineum. The fourchette (frenulum labiorum pudendi) (Fig. 1086) is the anterior edge of the perineum, and between it and the hymen is a depression, the fossa navicularis of the vulva or the vestibule of the vagina (fossa navicularis vestibuli vaginae) (Fig. 1086). The labia majora correspond to the scrotum in the male.

THE SMALL LIPS, NYMPHAE OR LABIA MINORA (LABIA MINORA PUDENDI) (Figs. 1085, 1086, 1087).

The small lips are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downward, outward, and back-
ward for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost in women who have borne children. In women who have not borne children they unite behind and usually form a fold (frenulum labiorum pudendi). Behind this fold is the fossa navicularis. Anteriorly, each lip divides into two limbs. The external limbs unite over the

glans clitoris to form the prepuce of the clitoris (praeputium clitoridis) (Fig. 1086). The internal limbs meet and unite beneath the glans clitoris and are attached to the under surface of the glans to form the fraenum (frenulum clitoridis). The nymphae are really modified skin. Their internal surfaces have numerous sebaceous follicles (glandulae vestibulares minores).

THE CLITORIS (Figs. 1086, 1087, 1089).

The clitoris is an erectile structure analogous to the corpora cavernosa of the penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It is connected to the rami of the os pubis. It consists of two corpora cavernosa, each of which (corpus cavernosum
clitoridis) passes behind into the crus (crus clitoridis). Each crus is attached to the ramus of the pubis and ischiium; the body (corpus clitoridis) is short and concealed beneath the labia; the free extremity (glans clitoridis) is a small rounded tubercle, consisting of spongy erectile tissue, and is highly sensitive. It is provided, like the penis, with a suspensory ligament (ligamentum suspensorium clitoridis), and with two small muscles, the Erectores clitoridis, which are inserted into the crura of the clitoris. The two corpora cavernosa are composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

To each crus of the clitoris goes a branch from the internal pudic artery, which branch is known as the deep artery of the clitoris. The dorsal arteries of the clitoris (arteriae dorsalis clitoridis) from the internal pudic send branches to the glans. The nerves of the clitoris consist of the dorsal nerves of the clitoris from the internal pudic nerve and sympathetic fibres from the hypogastric plexus.
THE VESTIBULE (VESTIBULUM VAGINAE).

The vestibule of English and American writers is a triangular smooth surface between the clitoris and the entrance of the vagina (Fig. 1086). It is bounded on each side by the nymphae. The vestibule of the vagina is understood by the Germans to be the space at the sides of the vaginal orifice enclosed by the labii minora, as well as the space in front of the vagina.¹

THE ORIFICE OF THE URETHRA OR THE MEATUS URINARIUS (ORIFICIUM URETHRAE EXTERNUM) (Figs. 1086, 1089).

The external orifice of the urethra or the meatus urinarius is situated at the back part of the vestibule, about an inch below the clitoris and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the meatus urinarius is the orifice of the vagina (orificium vaginae) (Fig. 1086), more or less closed in the virgin by a membranous fold, the hymen (Fig. 1086).

THE HYMEN (Figs. 1086, 1090).

The hymen varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called an imperforate hymen. Occa-

¹ See note 89 by Dr. M. Eden Paul, in vol. iv. of Toldt’s Atlas.
sionally the hymen is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After rupture of the hymen the small rounded elevations known as the carunculae myrtiformes are found as the remains of the structure.

GLANDS OF BARTHOLIN (GLANDULA VESTIBULARIS MAJOR [BARTHOLINI]) (Fig. 1089).

On each side of the posterior part of the commencement of the vagina is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper’s gland in the male. It is called the gland of Bartholin, the gland of Duverney, the vulvo-vaginal gland or the suburethral gland (glandula vestibularis major [Bartholini]). Bartholin’s gland lies partly in the inferior or anterior leaf of the triangular ligament. The posterior portion of the bulbous vestibuli and the Bulbo-cavernous muscle partly cover it. Each gland opens by means of a long single duct immediately external to the hymen, in the angle or groove between it and the nympha (Fig. 1090).
THE VAGINA

THE VAGINAL BULB OR BULB OF THE VESTIBULE (BULBUS VESTIBULI) (Fig. 1089).

Extending from the clitoris, along either side of the vestibule (the term vestibule being used according to the German nomenclature) (p. 1481), and lying a little behind the nymphae, are two large oblong masses, about an inch in length, consisting of a plexus of veins enclosed in a thin layer of fibrous membrane. This plexus is superficial to the triangular ligament, and it is covered externally and inferiorly by the Bulbo-cavernous muscle. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes; they are termed by Kobelt the bulbi vestibuli, and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front; it is called by Kobelt the pars intermedia, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb. The bulb receives its blood from the artery of the bulb (arteria bulbi vestibuli), which is a branch of the internal pudic.

INTERNAL ORGANS (PARTES GENITALES INTERNAE MULIEBRIS).

The internal organs of generation are—the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments.

THE VAGINA (Figs. 1084, 1087, 1093).

The vagina extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the pelvic outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches along its anterior wall (paries anterior), and three and a half inches along its posterior wall (paries posterior). It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal...
portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus (Fig. 1096).

The vaginal axis forms with the uterine axis an obtuse angle opening forward, and, as a rule, a little greater than a right angle (Fig. 1094). The fact that the attachment of the vagina to the cervix is above the external os causes the formation of a recess between the cervix and vaginal wall, known as the vaginal fornix (fornix vaginae). This recess is deeper posteriorly than it is laterally or in front. The anterior portion of the fornix is called the anterior fornix (Fig. 1087). The posterior portion is called the posterior fornix (Fig. 1087). The right and left portions are called the right and left lateral fornices. The vagina opens into the uro-genital cleft, between the labia minora and back of the urethra and clitoris. It opens by the vaginal orifice (orificium vaginae) (Fig. 1086). In the virgin the opening is partly closed by the hymen (p. 1481). After rupture of the hymen atrophied fragments of the torn membrane remain around the vaginal orifice, and are known as the carunculae myrtiformes (carunculae hymenales).

Relations (Figs. 1084 and 1087).—The upper part of the anterior wall of the vagina is in relation with the base of the bladder, being separated from that viscus by lax connective tissue. Lower down the middle line of the anterior wall and closely joined to it is the urethra. The upper part of the posterior wall, near the middle line, is covered for a quarter of an inch or more with peritoneum, which forms the anterior wall of the depths of the recto-vaginal pouch of peritoneum or pouch of Douglas (excavatio rectouterina [Douglas]) (Fig. 1096), between the uterus and vagina and the rectum. The portion of the posterior wall below the level of the pouch of Douglas is placed close to the rectum, a layer of pelvic fascia intervening. As the vaginal orifice is neared, the rectum and vagina separate, and interposed between them is a mass of fibro-fatty tissue called the perinæum or perineal body. Its sides are enclosed between the Levatores ani muscles. The ureter toward its termination (Fig. 1097) lies near the lateral wall of the vagina, passing at this point in a direction downward, inward, and slightly forward to reach the bladder. The vagina near its termination passes through the triangular ligament, and upon its sides are the bulbs of the vestibule, the glands of Bartholin, and the Bulbo-cavernous muscle.

Structure.—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

The Mucous Membrane (tunica mucosa) (Fig. 1093).—The mucous membrane is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the rugous columns of the vagina (columna rugarum anterior et posterior). The anterior column extends downward as far as the external orifice of the urethra, forming the carina urethralis vaginae. Numerous transverse ridges or rugae (rugae vaginales) extend outward from the raphé on either side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillae; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres from the muscular coat; it is regarded by Gussenbauer as an erectile tissue (see p. 1485). It contains a number of mucous crypts, but no true glands.

The Muscular Coat (tunica muscularis).—The muscular coat consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but
are connected by oblique decussating fasciculi which pass from the one layer to the other. Above the triangular ligament the fibres are non-striated; in the region of the ligament they show striations. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the sphincter vaginae (p. 461). External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The Erectile Tissue.—The erectile tissue consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; embedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

---

**Blood-vessels, Nerves, and Lymphatics.**—The arteries of the vagina are branches of the vesico-vaginal artery; the vaginal branch of the uterine artery (p. 687), and branches of the internal pudic and middle haemorrhoidal. The veins form an abundant plexus around the wall of the vagina and pass to the internal iliac veins. The lymphatics (Fig. 1091) arise from the two communicating networks, one of which is below the mucous membrane, the other in the muscular wall. There is a third network around the vaginal wall, from which the collectors arise. The trunks from the upper third of the vagina pass to the external iliac glands; those from the middle third pass to the internal iliac glands; those from the lower third terminate in the glands at the promontory of the sacrum or in the lateral sacral glands.¹ The nerves come from the third and fourth sacral nerves and from the utero-vaginal and vesical plexuses of the sympathetic.

---

¹ The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
THE WOMB OR UTERUS (Figs. 1084, 1087, 1088, 1092, 1097).

The uterus is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the foetus, and becoming the principal agent in its expulsion at the time of parturition. It is a hollow muscular organ. The non-pregnant uterus is contained in the cavity of the pelvis between the bladder and rectum (Figs. 1087 and 1088). It is rarely placed exactly in the mid-line, but inclines to one side or the other, more often to the left than to the right. The walls of the organ are extremely thick. The uterus is movable as a whole, and the body of the uterus is movable upon the neck. Its position varies with the condition of adjacent parts, especially the bladder and rectum. The cervix is more firmly fixed than the body and fundus, and hence the latter vary more in position than the former. Normally, in an erect individual, with the bladder and rectum empty, the external os is at the level of the upper surface of the pubic symphysis (Fig. 1084) and in a frontal plane passing through the ischiatic spines. The long axis of the uterus is directed forward and upward (Fig. 1084), and is angled where the body and cervix join. Hence, normally, with the bladder empty, the uterus is anteverted and anteflexed. When the bladder fills the antversion and anteflexion are almost abolished. If the bladder is overdistended and the rectum is empty, the uterus is pushed strongly backward, so that its long axis corresponds to the long axis of the vagina; in other words, it is retroverted.

In the virgin state it is pear-shaped, flattened from before backward, and is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below (Figs. 1092 and 1093). Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The non-pregnant adult uterus measures about three inches in length, two inches in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts (Fig. 1092): (1) An upper and larger portion, consisting of the body and fundus. This portion is flattened from before backward. (2) A lower, smaller, and cylindrical portion, the cervix.
The Fundus (*fundus uteri*) (Fig. 1092).—The fundus is the upper broad extremity of the uterus. If a line is drawn from the uterine opening of one Fallopian tube to the other, the portion above the line is the fundus. The fundus is directly continuous with the body.

The Body of the Uterus (*corpus uteri*) (Fig. 1092).—The body of the uterus is below and continuous with the fundus. In outline, when seen from in front or behind, it resembles a triangle, the base being above and the point being absent.

The anterior surface (*facies vesicalis*) passes on each side into the posterior surface (*facies intestinalis*) by the lateral border (*margo lateralis*).

The body gradually narrows from the fundus to the neck. Its anterior surface is so slightly rounded as to appear flattened. It is covered by peritoneum (Fig. 1092), which becomes separated from it at its union with the cervix, in order to form the utero-vesical pouch, which lies between the uterus and bladder (Fig. 1096). Its posterior surface is more rounded than the anterior, being convex transversely. It is
covered by peritoneum throughout (Fig. 1097), and separated from the rectum by some convolutions of the small intestine (Fig. 1087). The peritoneum which covers the posterior surface forms most of the anterior wall of Douglas's cul-de-sac (Figs. 853, 1096 and 1097, and p. 1248). Its lateral margins (Figs. 1092 and 1097) are concave, and each gives attachment to the Fallopian tube above, the round ligament below, and in front of this the ligament of the ovary; these structures lie between the layers of the broad ligament. The division between the

the body and the cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal called the internal os (Fig. 1095).

**The Neck or Cervix Uteri** (Figs. 1092 and 1095).—The neck or cervix uteri is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina (Figs. 1087, 1092, 1093, and 1096), which extends upward a greater distance behind than in front. The neck is spindle-shaped in those who have had no children, cylindrical in those who have had children.

---

**The Supravaginal Portion** (*portio supravaginalis cervicis*) (Figs. 1092 and 1096).—The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it.

**The Vaginal Portion** (*portio vaginalis cervicis*) (Figs. 1087, 1092, 1093, and 1096).—The vaginal portion is the lower end projecting into the vagina. It is round or
elliptical, the long axis of the elliptical figure being transversely placed. On its surface is a small aperture, the external mouth of the womb, or os uteri, or external os (orificium uteri externum) (Figs. 1092, 1093, 1095, and 1096), generally circular in shape, but sometimes oval or almost linear. If a woman has borne children the opening is transverse and the margins are irregular. The margin of the opening is, in the absence of past parturition or disease, quite smooth. This aperture divides the vaginal portion of the cervix into two lips, an upper or posterior lip (labium posterius) and a lower or anterior lip (labium anterius). On each side of the cervix and upper portion of the vagina there is a space containing bloodvessels and filled with loose cellular tissue. This loose tissue passes upward between the layers of the broad ligament and is called parametrium. On each side of the cervix and three-quarters of an inch away is the terminal portion of the corresponding ureter.

Folds and Ligaments.—The ligaments of the uterus are eight in number. Some are simple folds of peritoneum; others contain connective tissue and muscle. The ligaments are as follows: one anterior, one posterior, two lateral or broad, two sacro-uterine—all these being formed of peritoneum—and, lastly, two round ligaments.
The Anterior Ligament or the Utero-vesical Fold or Vesico-uterine Ligament is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body. It forms the utero-vesical pouch (excavatio vesicouterina) (Figs. 1096 and 1097).

The Posterior Ligament or the Recto-vaginal Fold passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch, called the recto-vaginal pouch or Douglas's pouch (Figs. 853, 1096, and 1097), the boundaries of which are, in front, the posterior wall of the uterus, the supravaginal portion of the cervix, and the upper fourth of the vagina; behind, the rectum and sacrum; above, the small intestine; and, laterally, the folds of Douglas or recto-uterine folds, which contain the sacro-uterine ligaments.

The Lateral or Broad Ligament (ligamentum latum uteri) (Figs. 1088, 1098, and 1104) is a peritoneal fold which passes from each side of the uterus to the lateral wall of the pelvis as high as the external iliac vein. From this region comes the peritoneal fold called the suspensory ligament of the ovary (Fig. 1088). The two broad ligaments form a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. In the uterus normally placed the anterior surface of the broad ligament faces forward and downward, and the posterior surface faces upward and backward. The ligament is more nearly vertical at its pelvic insertion. The two layers of the broad ligament are mostly near to each other, to the side and below they separate and pass into the peritoneum of the lateral pelvic wall, the bladder and the rectum. Between the two layers of each broad ligament are contained—(1) the Fallopian tube superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium or organ of Rosenmüller, and the paro-ophoron; (5) loose connective tissue, which is called parametrium; (6) unstripped muscular fibre; and (7) blood-vessels and nerves. The Fallopian tube is in the free edge of the broad ligament, and is contained in a special fold, which is attached to the part of the ligament near the ovary, and is known by the name of the mesosalpinx (Figs. 1094, 1098, and 1104). If the mesosalpinx is spread out, it is seen to be roughly triangular; the base of the triangle is outward, the apex at the upper and outer angle of the uterus; the upper boundary is the Fallopian tube, and the lower boundary is the ovary and its ligament. Between the two layers of the mesosalpinx are the parovarium and the paro-ophoron. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the infundibulo-pelvic ligament (Fig. 1103).
The ovary lies in a depression of the broad ligament called the **ovarian bursa** (*bursa ovarii*) (Figs. 1098 and 1104), and is joined to the ligament by a short fold, the **mesovarium** (Fig. 1104).

The **mesovarium** passes upward from the posterior surface of the broad ligament (Fig. 1098). Beneath the mesovarium is a larger and thicker portion of the broad ligament, called the **mesometrium** (Fig. 1098).

The **Sacro-uterine** or **Utero-sacral Ligaments** (*plicae rectouterinae*) are contained in the peritoneal folds of Douglas. They pass from the second and third bones of the sacrum, downward and forward on the lateral aspects of the rectum to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum. They contain fibrous tissue and unstriated muscle-fibre. Muscular fibres from the uterine wall to the rectal wall constitute the **Recto-uterinus muscle** (*musculus rectouterinus*). This muscle is part of the sacro-uterine ligaments.

A **Round Ligament** (*ligamentum teres*) (Figs. 1088, 1097, 1100, and 1104) is attached on each side of the uterus. The two ligaments are rounded cords, between four and five inches in length, each situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labium majus, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which in the foetus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the **canal of Nuck**. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which precedes the descent of the testis.

The **Cavity of the Uterus** (*cavum uteri*) (Fig. 1095).—The cavity of the uterus is small in comparison with the size of the organ, because of the great thickness of the wall. That portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its anterior and posterior walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of one division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, smaller and more nearly circular than the external os uteri, the **internal orifice of the uterus** or **internal os uteri** (*orificium internum uteri*) (Fig. 1095), which leads into the cavity of the cervix.

The **Cavity of the Cervix or Cervical Canal** (*canalis cervicis uteri*) (Fig. 1095).—The cavity of the cervix or cervical canal extends from the internal os uteri to the external os uteri. It is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name **uterine arbor vitae** (*plicae palmatae*) applied to it. These folds usually become very indistinct after the first labor.

**Structure.**—The uterus is composed of three coats: an external or serous coat, a middle or muscular coat, and an internal mucous or coat.

The **Serous Coat or Perimetrium** (*tunica serosa*) (Figs. 1087, 1092, 1096, and 1097).—The serous coat is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with
it, being separated from it by a layer of loose cellular tissue and some large veins. At the lateral margins of the uterus the serous coat passes on to the broad ligaments. The serous coat adheres closely to the uterus, and it is very difficult to separate it from the muscle.

The Muscular Coat (tunica muscularis) (Fig. 1095).—The muscular coat forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. The muscular tissue is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary; some passing at each side into the broad ligament, and others running backward from the cervix into the sacro-uterine ligaments. The fibres of the external portion of the outer layer (stratum subserosum) are longitudinal. The fibres of the inner portion of the outer layer (stratum supravasculare) are partly circular and partly longitudinal.

The middle layer of fibres (stratum vasculare), which is thickest, presents bundles of circular fibres closely connected with blood-vessels. In this layer are most of the blood-vessels. The circular fibres about the internal os form a distinct sphincter. Those which surround the orifices of the Fallopian tubes are arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus.

The internal or deep layer (stratum mucosum) consists of longitudinal fibres. Some consider the deeper portion of the muscular tissue of the uterus to be the muscularis mucosae. But the deep portion of the muscular substance is continuous with the more superficial portion, and there is no submucous coat between the muscle and the mucous membrane. The deeper layer of muscular fibres of the uterus contains connective tissue and elastic fibres. The muscular tissue of the cervix contains more connective and elastic tissue than does the body of the uterus; hence, the cervix is harder and stiffer than the body.

The Mucous Membrane (tunica mucosa) (Fig. 1095).—The mucous membrane is thin, smooth, and closely adherent to the subjacent muscular tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale-red color lined with columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat. In structure its corium differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue, in which run numerous large lymphatics. In it are the tube-like uterine glands (glandulae uterinae), which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance toward their closed extremities, which reach into the muscularis, and may be single or bifid. The uterine glands consist of a delicate membrane, lined with epithelium, which becomes ciliated toward the orifices.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphé, presenting an appearance which has
received the name of *arbor vitae*. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles (*glandulae cervicales uteri*), which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the *ovules of Naboth*. The mucous membrane covering the lower half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

The Uterus at Different Ages.—The uterus of the foetus is in the abdominal cavity. It is the brim of the pelvis. The cervix is considerably larger than the body. At birth the cervix is larger relatively than in the adult; there is no distinct internal os distinguishing the cavity of the body of the uterus from the cavity of the cervix, and "the arbor vitae extends throughout the whole length of the uterus."\(^1\) The growth of the uterus is slow until puberty is almost reached, when for a time the growth is rapid. The growth of the uterine body causes the mucous membrane of this part to lose its folds, hence the arbor vitae disappears from the body. In a woman who has had children the uterine cavity is larger than in a woman who has never borne a child. In advanced years the uterine wall becomes paler and hard and rigid from atrophic fibrous changes. A more distinct constriction separates the body and cervix. The internal os frequently and the external os occasionally are obliterated in old age.

Abnormalities.—Very rarely the uterine cavity is divided into two by a septum. Occasionally the condition known as *bicorne uter us* exists. In this condition each lateral angle is prolonged into a horn or cornu. The uterus is formed by the union of the two ducts of Müller, and failure of fusion of these ducts makes a double uterus or a bicornate uterus.

Changes at a Menstrual Period.—For several days before the menstrual flow begins the mucous membrane increases in thickness and vascularity and its surface is cast into folds. After these preparatory changes the superficial portions of the mucous membrane break down and are cast off, and bleeding begins. At the termination of menstruation the mucous membrane rapidly regenerates. At each menstrual period from 100 to 200 grammes of blood are discharged. The meaning of menstruation is uncertain. Pflüger believes the wall of the uterus is made raw, so that if an impregnated ovum arrives it will adhere. Reichert believes that menstruation means that no impregnated ovum has arrived in the womb, and hence no bed is needed for one.

Changes Induced by Pregnancy.—The muscular fibres hypertrophy enormously and become vastly longer and broader. There is a great increase in connective tissue, and new connective-tissue fibres pass between bundles of muscle. The peritoneal coat undergoes hyperplasia: It remains closely adherent to the uterus, except over the lower segment, from which region it can be easily stripped. The blood-vessels become large and tortuous. The nerves are increased in length and new filaments form. The lymphatics undergo hypertrophy and hyperplasia (Prof. Barton Cooke Hirst). The uterus becomes spherical, and after the fourth month ovoidal. Early in pregnancy the increase in weight causes the uterus to descend in the pelvis. After the third month it rises progressively, and during the ninth month the fundus reaches the epigastrium. "Before term (four weeks in primiparae, ten days or one week in multiparae) the fundus sinks again, as the presenting part and lower uterine segment become engaged in the pelvic cavity. This phenomenon is explained by contraction of the overstretched abdominal walls."\(^2\) The womb is acutely anteflexed during the first three months

---

1 Prof. Francis A. Dixon in Prof. Cunningham's Text-book of Anatomy.
of pregnancy. After this period, as the womb rises, the anteflexion is diminished, but some degree remains, because the abdominal walls are too lax to hold the organ straight. The uterus passes somewhat to the right side and undergoes a rotation on its longitudinal axis, so that the anterior surface looks front and to the right. These changes in position are caused by fecal distention of the sigmoid. The intestines are above and back of the uterus. During the first four months the cervix softens and enlarges somewhat. The length of the cervical canal is not altered during pregnancy, and the canal does not dilate until labor begins. During pregnancy the cervical glands secrete thick mucus, which coagulates and occludes the cervical canal; the round ligaments become stronger, and the layers of the broad ligament are separated toward their inner portions by the enlarging womb.
After parturition the uterus nearly regains its former size, usually weighing something over one and a half ounces; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are very tortuous, and its muscular layers are more defined.

Vessels and Nerves (Fig. 1100).—The arteries of the uterus are the uterine, from the internal iliac, and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The uterine artery reaches the lower part of the uterus at the side and is pro-

![Diagram of the female reproductive system](image)

**Fig. 1102.**—The lymphatics of the internal organs of generation in the female. (Poirier and Charpy.)

longed as a large artery to the body and fundus, which ascends between the layers of the broad ligament. The uterine artery gives off a smaller branch, the cervical, which descends to supply the cervix and sends cervico-vaginal branches to the vagina. The azygos arteries of the vagina come from the cervico-vaginal reinforced by branches of the vaginal arteries (Fig. 1104). A median longitudinal vessel is formed in front and behind, which descends in the vaginal wall. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus. Dr. Byron Robinson, instead of describing the uterine and ovarian
arteries as two vessels, describes them as parts of one vessel, the *arteria uterina ovarica* (p. 558). The veins are of large size, and correspond with the arteries. In the impregnated uterus these vessels form the *uterine sinuses*, consisting of the lining membrane of the veins adhering to the walls of the canals channelled through the substance of the uterus. They terminate in the *uterine pleuses*, which empty into the *internal iliac veins*. The lymphatics (Figs. 1101 and 1102) originate from three networks, a muscular network, a peritoneal network, and a network in the stroma. The trunks from these networks anastomose, and thus form another network beneath the peritoneum, and from the fourth network the collectors arise. The network of the cervix is continuous with that of the body. The collecting trunks from the cervical region number from five to eight. Some terminate in the *external iliac glands*, some in the *internal iliac glands*, some in the lateral sacral glands, or the glands of the promontory. The collecting trunks from the body terminate chiefly in the *juxta-aortic* or *pre-aortic glands*, but some terminate in the *external iliac glands*, and some in the *inguinal glands*.\(^1\) The nerves come chiefly from the *uto- vaginal plexus*, which continues into the *hypogastric plexus* and receives filaments from the *third* and *fourth sacral nerves*. The uterus also receives direct fibres from the *hypogastric plexus* and from the *vesical plexus*.

**Surgical Anatomy.—** *Pelvic cellulitis* (*parametritis*) is inflammation of the pelvic cellular tissue. It is due to sepsis, and its usual antecedent is uterine sepsis. A laceration of the cervix may admit bacteria. An abscess may form. If it points in the vagina it should be incised through the vaginal wall. The uterus may require removal (*hysterectomy*) in cases of *malignant disease* or for *fibroid tumors*. *Carcinoma* is the most common form of malignant disease of the uterus, though cases of *sarcoma* do occur. Carcinoma may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous membrane covering of the vaginal surface of the cervix. The columnar form may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section. The former operation is attended by the smaller death-rate. Vaginal hysterectomy may be performed in any case in which the uterus or the uterus and tumor are not too large to be withdrawn through the vagina. It is difficult in this operation to deal with adhesions and other complications in the upper part of the pelvis, and for this reason many surgeons prefer the abdominal operation. *Vaginal hysterectomy* is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum into the vagina. The cervix is then seized with a volsellum and pulled down as far as possible and the mucous membrane of the vagina incised around the cervix as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. A pair of dressing forceps are then pushed through into Douglas's pouch and opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesico-uterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues off the anterior uterine wall. When the vesico-uterine pouch has been opened and the opening dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas's pouch and an aneurism needle, armed with a long silk ligature, is inserted into the vesico-uterine pouch, and is pushed through the broad ligament of one side about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery, enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably farther down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. This canal is then sponged out and lightly dressed with gauze.

\(^1\) The Lymphatics. By Poirier, Cunéo, and Delamarre. Translated and edited by Cecil H. Leaf.
THE FALLOPIAN TUBE

no sutures being used. The gauze may be removed at the end of the second day. In squamous epithelioma, amputation of the cervix is done by some in those cases where the disease is recognized before it has invaded the walls of the vagina or the neighboring broad ligaments. The operation consists in removing a wedge-shaped piece of the uterus, including the cervix, through the vagina and attaching the cut surfaces of the stump to the anterior and posterior vaginal walls, so as to prevent retraction. In view, however, of the continuity of the lymphatic network of the cervix with the lymphatics of the body, the operation is insufficient and should be condemned. Complete abdominal hysterectomy is rarely necessary, except for malignant disease. In this operation the entire uterus is removed. The preliminary introduction of bougies into the ureters as practised by Kelly and Clark enables the surgeon to readily recognize the situations of these tubes. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a similar manner to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is cut across. The uterus is now turned forward and the peritoneum at the bottom of Douglas's pouch incised transversely, and the posterior wall of the vagina cut across until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is usually left unsutured. In some cases of uterine fibroid the abdomen is opened and the tumor is removed, but the uterus is not taken away. This operation is called myomectomy. This operation is suited only to solitary subperitoneal or interstitial tumors (Penrose).

The common operation for uterine fibroids is supravaginal amputation. The uterus is cut away and the cervical flaps are sutured. Before the technique of hysterectomy was perfected and before myomectomy was devised the favorite operation for uterine fibroids was salpingo-oophorectomy, and by it a large majority of cases operated upon were cured. When it succeeds a premature menopause is induced and the tumor shrinks. The operation is useless if a woman is past the menopause, and is apt to fail if the tumor is very soft or very large.

THE ADNEXA OR APPENDAGES OF THE UTERUS.

The appendages of the uterus are the Fallopian tubes, the ovaries and ovarian ligaments, and the round ligaments. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

THE FALLOPIAN TUBE (TUBA UTERINA [FALLOPII])
(Figs. 1092, 1097, 1098, 1103, 1104).

The Fallopian tubes or oviducts convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches and a quarter in length, and is placed in a fold of peritoneum, which is part of the broad ligament and is called the mesosalpinx (Fig. 1008). Each tube is described as consisting of four portions: (1) the isthmus (isthmus tubae uterinae) (Fig. 1103), or inner constricted third; (2) the ampulla (ampulla tubae uterinae) (Fig. 1103), or outer dilated portion, which curves over the ovary; and (3) the infundibulum, the funnel-like expansion of the tube, at the bottom of which is the abdominal orifice or pavilion (ostium abdominale tubae uterinae) (Fig. 1103). The abdominal orifice has a small diameter (2 mm. when relaxed to its full extent). The margin of the infundibulum is rendered irregular by the presence of numerous small processes, the fimbriae (fimbriae tubae). This end of the tube is called the fimbriated extremity (Fig. 1103), because of these processes. The surfaces of the fimbriae looking into the cavity of the infundibulum are covered with mucous membrane continuous with the tubal mucous
membrane. The outer surfaces are covered with peritoneum. One of the fimbriae is attached to the ovary and is called the ovarian fimbria (fimbria ovarica) (Fig. 1103). (4) The uterine portion of the tube (pars uterina) (Fig. 1095) is in the uterine wall. The opening into the uterus (ostium uterinum tubae) is even smaller than the abdominal opening, and will admit only a small bristle. The general direction of the Fallopian tube is outward, backward, and downward. In connection with the fimbriae of the Fallopian tube or with the broad ligament close to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the hydatids of Morgagni (appendices vesiculosis). They are representative of small portions of the upper extremity of the Wolffian duct.

**Course Pursued by the Fallopian Tube** (Figs. 1088 and 1103).—The tube on each side begins at the upper and outer angle of the uterus and passes outward in a horizontal direction toward the uterine extremity of the ovary. It then bends almost to a right angle and ascends close to the pelvic wall and in front of the anterior margin to the tubal extremity of the ovary. At this point it turns sharply downward and a little backward, and the inner surface of the infundibulum comes to lie upon the free margin and the posterior portion of the inner surface of the ovary. "The fimbria ovarica thus ascends in a recurrent direction to the extremitas tubaria.''

**Structure.**—The Fallopian tube consists of three coats—serous, muscular, and mucous.

The **external or serous coat** (tunica serosa) (Fig. 1098) is peritoneal. Beneath this lies the *tunica adventitia*, composed of lax connective tissue.

The **middle or muscular coat** (tunica muscularis) consists of an external longitudinal layer (stratum longitudinalae), and an internal circular layer (stratum circulare) of muscular fibres continuous with those of the uterus.

The **internal or mucous coat** (tunica mucosa) is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds (plicae tubariae), which in the outer, larger part of the tube or ampulla (plicae ampullares) are much more extensive than in the narrow canal of the isthmus (plicae isthmicae). The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surface of the

---

fimbriae, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

Vessels and Nerves.—The chief artery of the tube is the tubal branch of the uterine artery (ramus tubarius) (Fig. 1100). It also receives branches from the ovarian (Fig. 1100). Some of the tubal veins empty into the uterine veins, some into the ovarian veins. The lymphatics (Figs. 1101 and 1102) coming from the tube unite with the trunks coming from the uterus and ovary and terminate in the juxta-aortic glands. The nerves come from the same plexuses that send branches to the uterus and ovary.

The Epo-ophoron, Parovarium or Organ of Rosenmüller (Figs. 1094, 1095, and 1103) is placed in the mesosalpinx, between the ovary and tube. It consists of a number of epithelial-lined closed tubes. This structure can be readily seen if the mesosalpinx is stretched and held in front of the light. One of these tubes runs parallel to the fallopian tube and is called Gärnter’s duct (ductus epitophori longitudinalis). A number of tubes (ductuli transversi) ascend from near the ovary and each empties into Gärnter’s duct at a right angle. Gärnter’s duct is a portion of the Wolffian duct, which has persisted and is represented in the male by the canal of the epididymis. The tubules which join the duct “are derived from the mesonephros and represent the vasa efferentia and coni vasculosi of the testis, and probably also the ductuli aberrantes of the canal of the epididymis.”

The Paro-ophoron is within the mesosalpinx, but is nearer to the uterus than is the epi-ophoron. It consists of several small tubules, which can be seen in an adult only by the aid of a pocket lens. They are visible to the naked eye in a child at birth. It represents the organ of Giraldés in the male and is derived from the mesonephros.

THE OVARY (Figs. 1088, 1092, 1094, 1095, 1097, 1098, 1099, 1103, 1104).

The ovaries (ovaria), the testes muliebres of Galen, are two in number and are analogous to the testes in the male. They are oval-shaped bodies of an elongated

1 Prof. Cunningham’s Text-book of Human Anatomy.
form, flattened from above downward, situated one on each side of the uterus, in the posterior layer of the broad ligament behind and below the Fallopian tube. Each ovary is connected by its anterior straight margin to the broad ligament; by its lower extremity to the uterus by a proper ligament, the ligament of the ovary (ligamentum ovarii proprium) (Fig. 1103); and by its upper end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria (fimbria ovarica) (Fig. 1103), its mesial and lateral surfaces and posterior convex border are free (Fig. 1104). The ovaries are of a grayish-pink color, and present either a smooth or a puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weigh from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers are in conflict as to what is to be regarded as the normal position. The fact appears to be that the ovary is differently placed in different individuals. The two ovaries are seldom placed in absolutely identical positions. Hasse has described the ovary as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultz, on the other hand, believes that its long axis is antero-posterior. Kölliker asserts that the truth lies between these views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament. When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriae pass upward on to the ovary and closely embrace it.

Waldeyer states, as the result of the examination of fifty female subjects, ranging from early childhood to advanced age, that the ovary "lies on the lateral pelvic wall and vertically when the woman takes the erect posture." Its tubal extremity is near the external iliac vein; its uterine end is directed downward, while the Fallopian tube overlies it so as to cover it on its medial face entirely or nearly so. Its convex margin looks downward and backward toward the pelvic cavity and rectum, while its straight margin or hilum lies laterally on the pelvic wall attached to the mesosalpinx. He also finds that it lies in a distinct but shallow groove (fossa ovarii) limited above by the hypogastric artery and below by the ureter, in such a manner that the ureter lies along the convex margin of the ovary, and the hypogastric artery passes near the hilum or straight margin.

The ovary possesses two poles or extremities: (1) An outer, superior or tubal extremity (extremitas tubaria ovarii). (2) An inner, inferior or uterine extremity (extremitas uterina ovarii). The ovary has two surfaces, an inner surface (facies medialis), which is also upper; an outer surface (facies lateralis), which is also lower. The posterior or free border (margo liber) is markedly convex. The anterior

---

border (margo mesovaricus) is almost straight and is narrow. The anterior border
is not free, but is joined to the posterior layer of the broad ligament by a peritoneal
fold known as the mesovarium. There is a groove in the anterior border called the
hilum (hilus ovarii), through which vessels and nerves to pass, and emerge from
the ovary.

Supports and Connections of the Ovary.

From its upper extremity a peritoneal fold is continuous with the peritoneum
over the iliac vessels and Psoas muscle. It is called the ovario-pelvic fold or the
suspensory ligament (ligamentum suspensorium ovarii) (Fig. 1088). It is in reality
a portion of the broad ligament, and within it are the ovarian vessels and nerves.
The vessels (Fig. 1104) and nerves go to the anterior border of the ovary and are
surrounded by a peritoneal sheath derived from the posterior layer of the broad
ligament; it is thus evident that the anterior border of the ovary is connected to
the posterior portion of the broad ligament by a very short mesentery, the meso-
varium¹ (Fig. 1098). The ligament of the ovary or ovarian ligament (Figs. 1088
and 1103) is a round, cord-like structure, composed chiefly of non-striated muscle-
fibres, which passes between the two folds of the broad ligament from the lower
extremity of the ovary to the lateral angle of the uterus. The ovarian fimbrìa
(Fig. 1103), as previously stated, passes to the upper extremity of the ovary
from the extremity of the Fallopian tube.

The Descent of the Ovary.

In the female there is a gubernaculum which effects a considerable change in
the position of the ovary, though not so extensive a change as is effected upon the
male testicle. The gubernaculum in the female, as it lies on either side in con-
tact with the fundus of the uterus formed by the union of the Müllerian ducts,
contracts adhesions to this organ and thus the ovary is prevented from descending
below this level. The remains of the gubernaculum—that is to say, the part
between the attachment of the cord to the uterus to its termination in the labium
majus—ultimately forms the round ligament of the uterus. A pouch of peri-
toneum accompanies it along the inguinal canal, analogous to the funicular process
in the male; it is called the canal of Nuck. In rare cases the gubernaculum fails
to contract adhesions to the uterus, and then the ovary descends through the
inguinal canal into the labium majus, extending down the canal of Nuck. Under
these conditions, the position of the ovary resembles the position of the tes-
ticle in the male.

The Ovary at Different Ages.—The ovary of childhood is smooth and
even. The rupture of Graafian follicles, repeated many times, causes the surface
of the ovary to become pitted, puckered, fibrous, and uneven in old age. The sur-
fave of the ovary is grayish-red in color. The corpus luteum of a non-pregnant
woman slowly degenerates and disappears. The corpus luteum of an impreg-
nated woman enlarges during pregnancy.

Structure (Figs. 1098, 1099, 1105, and 1106).—The ovary consists of a number of
Graafian follicles or vesicles embedded in the meshes of a stroma or framework,
and invested by a serous covering derived from the peritoneum.

Serous Covering.—Though the investing membrane of the ovary is continuous
with the peritoneum near the hilum of the ovary (the point of junction being
indicated by a narrow white line), it differs essentially from the peritoneum,
inasmuch as it is an epithelial structure and consists of a single layer of columnar
epithelial cells, instead of the flattened endothelial cells of other parts of the

¹ Prof. Cunningham's Text-book of Anatomy.
membrane; this has been termed the germinal epithelium of Waldeyer, and gives to the surface of the ovary a dull-gray aspect instead of the shining smoothness of serous membranes generally.

Stroma.—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, which, indeed, they most resemble (Hils); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the tunica albuginea, but is nothing more than a condensed layer of the stroma of the ovary.

Graafian Follicles or Vesicles (folliculi oophorici vesiculorum [Graaf]) (Figs. 1105 and 1106).—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the Graafian vesicles or ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles of uniform size, about \( \frac{1}{100} \) of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the cortical layer. They are especially numerous in the ovary of the young child. After puberty and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also corpora lutea, the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum other large and mature Graafian vesicles are found embedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the medullary substance (zona vasculosa [Waldeyeri]). This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The larger Graafian follicles consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named the oviscapsule, which is lined by a layer of nucleated cells, called the membrana granulosa. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the membrana granulosa are collected into a mass which projects into the cavity of the vesicle. This is termed the discus proligerus, and in this the ovum is embedded.

The ova are formed from the germinal epithelium on the surface of the ovary.
This becomes thickened, and in it are seen some cells which are larger and more rounded than the rest; these are termed the **primordial ova**. The germinal epithelium grows downward in the form of tubes or columns, termed the **egg tubes** of Pflüger, into the ovarian stroma, which grows outward between the tubes, and ultimately cuts them off from the germinal epithelium. These tubes are further subdivided into rounded **nests** or **groups**, each containing a primordial ovum which undergoes further development and growth, while the surrounding cells of the nest form the epithelium of the Graafian follicle.

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman’s life, while their formation commences before birth. Before puberty the ova are small, the Graafian vesicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear. At puberty the ova enlarge and become more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

**Discharge of the Ovum.**—The Graafian vesicles, after gradually approaching the surface of the ovary, burst; the ovum and fluid contents of the vesicles are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube. This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.

In the fetus the ova are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

**The Round Ligament** (p. 1491).

**Vessels and Nerves.**—The **arteries of the ovaries** (Figs. 1100 and 1104) are the **ovarian** from the aorta, corresponding to the spermatic arteries in the male. The ovarian artery on each side enters the pelvis in the fold of broad ligament known as the suspensory ligament of the ovary and enters the attached border, or hilum, of the ovary. The ovarian vessels anastomose about the hilum with branches of the **uterine artery**. The **veins** follow the course of the arteries; they form a plexus near the ovary, the **pampiniform plexus**, corresponding to a like structure near the male testicle. The **lymphatics** (Figs. 1101 and 1102) terminate in the glands to the corresponding side of the aorta, and they anastomose in their course with trunks from the uterine fundus and Fallopian tube. The **nerves** come from the **ovarian plexus**, which is a continuation of the **renal plexus** along the ovarian artery, and from the **aortic plexus**.

**Surgical Anatomy of the Appendages.**—**Extra-uterine pregnancy** most commonly occurs in the ampulla of the tube. The product of the conception may escape through the ostium abdominale or the walls of the tube may rupture, a violent hemorrhage resulting. **Pelvic peritonitis** is a not uncommon sequence of tubal disease. **Salpingitis** is inflammation of the mucous coat of the tube—**interstitial salpingitis** of the middle coat, **perisalpingitis** of the peritoneal coat.

If inflammation closes the uterine and the abdominal ends of the tube, mucus gathers and distends the tube (**hydroosalpinx**). If purulent matter gathers, the condition is known as **pyosalpinx**. An ovary may fail to descend and remain well above the pelvic brim; it may **prolapse** into Douglas’s pouch; it may enter the sac of a hernia; it may inflame; a **tumor** or **cyst** may arise from it. A **solid tumor** of the ovary may be a fibroma, a sarcoma, or a carcinoma. “**Cysts** may originate in any part of the tubo-ovarian structure; as the cortical, medullary, or parenchymatous portions of the ovary; in the structure between the tube and ovary known as the Rosenmüller organ or parovarian structures; and in the hydatid of Morgagni.”1 **Cysts** may be simple, proliferating, or dermoid; unilocular or multilocular. Glandular proliferous cysts, papillary pro-

---

liferous cysts, dermoid cysts, and parovarian cysts may attain a large or even an enormous size. The operation for the removal of an ovarian cyst is one of the most successful of the major procedures of surgery.

**THE MAMMARY GLAND (MAMMA)** (Figs. 1107, 1108, 1109, 1110).

The *breasts, mammary glands* or *mammae* secrete the milk, and are accessory glands of the generative system. They develop fully in the female, but remain permanently rudimentary in the male. There are two of these glands, and they are situated in the superficial fascia of the anterior portion of the thorax. Between the two glands and in front of the sternum is a groove, the *bosom*.

**Description of a Well-developed Breast.**—Each gland appears as a hemispherical body projecting from the front of the thorax beneath the skin and lying over a portion of the Pectoralis major muscle and a smaller portion of the Serratus magnus muscle. The hemispherical projection extends usually from the margin of the sternum to the axilla and from the level of the second rib to the level of the sixth rib, or from the third rib to the seventh rib, but this does not represent the real size of the gland. The gland is much larger than this, being rendered so by tails or prolongations of breast tissue, which will be described later (p. 1505).

**The Nipple (papilla mammae)** (Figs. 1107, 1108, 1109, and 1110).—The nipple projects from a little below and to the median side of the summit of the hemisphere at or above the level of the fifth rib, and is covered with thin skin. The right nipple may not exactly correspond in situation and direction to the left nipple. The nipple varies considerably in height and shape. In the virgin it is usually cylindrical and is directed forward and slightly upward and outward. The apex of the nipple is rendered rough by fissures (Fig. 1107), it exhibits a depression in which are the openings of the milk ducts (Fig. 1109), and its circumference is thrown into *concentric ridges* (Fig. 1109). The nipple is surrounded by a darker circular wrinkled area, the *areola (areola mammae)* (Figs. 1107 and 1108), in which are sweat-glands and on which are twelve or fifteen small rounded elevations. These elevations are caused by cutaneous sebaceous glands which in structure represent a transition between sebaceous and mammary glands. They are probably rudimentary portions of the mammary gland and are known as the *glands of Montgomery (glandulae areolares)* (Fig. 1109). The color of the nipple and areola varies with the complexion of the individual. In brunettes it is darker than in blondes. The usual color of the nipple in a young woman is rosy-pink, the areola being of a darker shade. During the early months of pregnancy the nipple and areola become dark brown in color, the areola becomes larger in circumference and the glands of Montgomery increase in size (Fig. 1110). The nipple contains non-striated muscle and mechanical irritation or sexual excitement makes it stiff and erect. The skin covering the breast is clear, soft, and delicate, and subcutaneous veins are often visible. The skin of the nipple and areola is particularly delicate.

**Variations in the Mammæ.**—Before puberty the glands are small, of the infantile type, grow slowly, and differ but slightly from the male organs. The nipple is small and flat and pale. At puberty the increase in the size of the breast is rapid and considerable, due to growth of gland tissue and of subcutaneous fat. During pregnancy the breasts enlarge greatly and remain very large throughout lactation. This enlargement is due to new gland tissue and increased vascularity. Numerous blue veins are visible in the skin, the areola darkens, and the glands of Montgomery enlarge (Fig. 1110). During lactation the associated lymphatic glands may enlarge (A. Marmaduke Shield). After the termination of lactation the breasts diminish in size. They do not become as small as the virgin breast, are apt to lose their hemispherical outlines, and cease to be soft. They droop as flaccid pendulous
masses, the subcutaneous fat is largely gone, and the outlines of the lobular breast tissue can be seen and felt. The nipple is long and hangs down like a teat. At the menopause the breast usually shrinks. In some cases, however, it actually increases in size. In such a case, although the gland atrophies, there is an extensive deposit of fat. In old age the glands undergo atrophy and largely disappear, the skin is flabby and thrown into wrinkles, and the breasts contain very little glandular structure, and are hard from the presence of fibrous tissue. The nipples become pigmented and corrugated. Women vary greatly in the development of the breasts. In some women they are large, firm, and well proportioned; in others they are small, flat, or atrophy occurs in the course of certain bodily diseases, as phthisis, and certain mental diseases, as melancholia. If the ovaries are ill-developed the breasts remain flat and small. In newly married women, even though pregnancy does not exist, the breasts often develop decidedly and rapidly. The outline and direction of the breast and also of the nipple may be altered by corsets. The left mamma is usually somewhat larger than the right.

One gland or both glands may be entirely absent, the nipple being also absent. One or both glands may be absent, one or both nipples being present. When there is only one nipple, it is apt to be the left. The term polymazia (mammae accessoriae muliebris) means the presence of supernumerary breasts, with or without nipples. Polythelia means the presence of supernumerary nipples, the associated glandular structure being rudimentary. There may be one, two, or several supernumerary breasts, and when more than one exists, are usually asymmetrical. If one is functionally active, it enlarges during pregnancy and furnishes milk.

Supernumerary mammæ may secrete milk or may be without function. The most common situation is on the part of the chest below and to the inner side of the normally placed gland. They may also exist in the axilla, the abdomen, the groin, the back, and the thigh. Many cases of supposed supernumerary glands have been really instances in which moles, warts, or sebaceous cysts have been mistaken for breast tissue, but some cases are undoubted.

Fig. 1107.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)
Prolongations of Mammary Tissue.—As previously stated, the outlines of the breast are not regular, but here and there tails, prolongations, or cusps come off from and are true portions of the gland. Two or even more prolongations pass to the edge of the sternum; others pass toward the axilla, the clavicle, and the origin of the external oblique muscle from the ribs. Underneath the mammary gland prolongations of mammary tissue penetrate the pectoral fascia (Heidenhain).
If one of the glandular cusps is of considerable size it is called an outlying lobule.

Structure of Mammary Gland and Nipple (Figs. 1107 and 1108).—The glands of the breast (corpus mammae) rest by a smooth posterior surface upon the loose pectoral fascia, which fastens the breast to the muscle beneath, but so loosely that the breast is movable. The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes, of fatty tissue in the intervals between the lobes, of retinacula, and of skin. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, in general circular in form, with prolongations here and there, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. On the anterior surface there are many irregular elevated processes with deep spaces between them. From the summits of the elevations connective-tissue strands (retinacula cutis) pass to the true skin. The glandular structure consists of numerous lobes (lobi mammae), and these are composed of lobules (lobuli mammae), connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli (Fig. 1107), which open into the smallest branches of the excretory ducts; these ducts, uniting, form larger ducts, which terminate in single canals. Each canal is called a lactiferous, galactophorus or mamillary duct (ductus lactiferus) (Fig. 1107). Each lobe possesses one lactiferous duct. This passes to the apex of the lobe and then into the nipple. The lactiferous ducts are white and cord-like, and contrast with the yellowish-red tissue of the gland itself. The number of excretory ducts varies from fifteen to twenty. They converge toward the areola, beneath which each duct forms a spindle-shaped dilatation, the ampulla (sinus lactiferans) (Fig. 1107). The ampullae serve as reservoirs for the milk. At the base of the nipple the ducts become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. Each orifice (porus lactiferus) is the orifice of a tube which drains an individual lobe. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres; muscular fibres are entirely absent; their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or nursing the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of an alveolus undergo fatty degeneration, and are eliminated in the first milk as colostrum-corpuscles. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells lining the limiting membra propria. The single nucleus of each cell divides and forms two. In the protoplasm, especially in the end of the cells toward the alveolus, drops of fat appear, and the nucleus toward this end of the cell also becomes fatty.

The end of the cell toward the alveolus breaks down, and the liberated material constitutes "the albuminous ingredients of the milk, while the drops of fat become the milk-globules. The portion of the cell which remains forms new cytoplasm, and the same process is repeated over and over again. The cells also secrete water and the salts which are found in the milk."1

The fibrous tissue (Fig. 1108) invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The fatty tissue (Figs. 1107 and 1108) surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abun-

---

1 Human Physiology. By Joseph Howard Raymond.
dance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Fig. 1111.—The lymphatic vessels of the anterior surface of the breast; the subareolar plexus and the trunks which run from it. (Sappey.)

**Vessels and Nerves.**—The arteries supplying the mammary gland are derived from the perforating branches of the internal mammary, long thoracic branches of the...
axillary, and branches from the intercostals. The veins describe an anastomotic circle around the base of the nipple, called by Haller the circulus venosus. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The lymphatics of the mammary gland (Figs. 1111 and 1112) and mammary region have been previously described (pp. 812, 813, and 814). The nerves are derived from the fourth, fifth, and sixth intercostal nerves, and sympathetic filaments from the dorsal cord pass to the breast along the branches of the intercostal nerves.

Surgical Anatomy.—Occasionally the mammary gland undergoes enormous hypertrophy. This may occur at any age, even in the virgin. The physiological enlargement of puberty may become excessive or the physiological enlargement of pregnancy and lactation may continue and increase after the termination of lactation. The chief elements in the enlargement are fat and connective tissue, and it is doubtful if there is extensive reproduction of glandular tissue.

Abscess of the breast may occur at any age, but is most common by far in nursing women. The portals are opened to infection by a crack in the nipple and bacteria are carried inward by the lymph-vessels. In some cases the pus gathers beneath the skin (supra-mammary abscess), in others in the breast tissue (intra-mammary abscess). In rare cases pus gathers beneath the breast (retro-mammary abscess). In intra-mammary abscess the pus burrows through the fibrous septa or fascia and forms numerous channels, and such a channel is constricted at the point where it passes through fascia or a fibrous septum, as an hour-glass is constricted.

In every patient suffering from abscess the nipple should be examined for a sore or crack, and the area when found should be treated antiseptically. A supra-mammary abscess should be opened by an incision radiating from the nipple.

In intra-mammary abscess follow the advice of Sheild: open the abscess by an incision radiating from the nipple, insert the index finger, and when possible pass it to the bottom of the abscess and carry the tip from the depths of the abscess to as near the surface as possible. At this point make a counter opening. The finger breaks down septa which cause constriction and thus converts the tracking sinuses into one large cavity. Drain by tubes.

A retro-mammary abscess is opened by an incision, following the outline of the breast at the thoraco-mammary junction, the finger being pushed through the incision and up under the gland.

Tuberculosis of the breast may occur, and if it does, cold abscess is apt to form. The best treatment is removal of the gland and the associated lymph glands.

Chronic mastitis is a condition of mammary fibrosis, most common in neurotic single women, and apt to be associated with ovarian or uterine disease.

Malignant dermatitis or Paget’s disease of the nipple is a chronic condition consisting of epithelial proliferation, induration, desquamation, and ulceration, and it is apt to be followed by epithelioma.

Chancre of the nipple is occasionally met with.

Secondary and tertiary syphilitic lesions are seen upon the skin of the breast, the nipple, and the areola.

Cysts and tumors are common in the breast.

There may be cystic degeneration of the gland in women near the menopause (involution cysts); a lacteal cyst; a hydatid cyst; an adenoma may become cystic.

The nipple may suffer from epithelioma, myoma, myxoma, angioma, papilloma, or fibroma.

The innocent tumors of the breast are fibro-adenoma, cystic adenoma, myxoma, and angioma.

The skin of the breast may suffer from any form of growth or cyst which could arise from the skin of another part. Malignant tumors of the glandular structure are ten times as frequent as innocent tumors. Sarcoma is rare; carcinoma is very common.

Carcinoma of the breast has occupied much of the attention of surgeons during recent years. The old operation was uniformly followed by recurrence. The modern radical operation has been evolved from the studies of Moore, the younger Gross, Heidenhain, Stiles, Banks, Halsted, and others. The modern operation always removes at least the skin and subcutaneous tissue over the hemispherical portion of the breast, the underlying lobules of the breast, the pectoral fascia, and the sternal portion of the great Pectoral muscle, the lymphatic tracts from the breast, the lymphatic glands and cellular tissue from the axilla, and from beneath the latissimus dorsi muscle.

The pectoral fascia and the sternal portion of the great Pectoral muscle must come away in every case, because breast tissue may pass through the fascia. The entire breast must be removed, because even in a recent case the entire breast is regarded as infected. The clavicular portion of the great Pectoral muscle is anatomically distinct from the sternal portion and its removal is not imperative. Some operators remove the lesser Pectoral muscle. To leave it is of no value to the arm, and it frequently causes an annoying rigid band anterior to the axilla. To take it away

1 Diseases of the Breast. By A. Marmaduke Sheild.
gives ready access to the axillary vessels at a desirable point above. The sheath of the axillary vein should be removed with the glands and cellular tissue of the axilla. The glands receiving lymph from the cancerous area must be removed, of course. In view of the fact that in an undetermined percentage of cases a lymph tract passes direct to the subclavian glands, it is evident that these glands may become infected by this route instead of, as is more usual, secondarily to axillary infection; hence it seems wiser in every case to remove the cellular tissue and glands from the subclavian triangle. All of these structures should be removed as one piece, in order to avoid cutting across lymph tracts and flooding the wound with carcinoma cells which might adhere, grow, and reproduce cancer.

Halsted’s operation is the method adopted by most surgeons. The wound cannot be completely closed, and the raw spot is covered at once or later with Thiersch skin grafts. (For surgical considerations regarding the lymphatics in mammary carcinoma see page 814.)

The Male Breast (*mamma virilis*).—The male breast is a small flat structure, consisting chiefly of connective tissue, but containing some branched tubules. Under normal circumstances it remains permanently of the infantile type. It possesses a nipple which is much smaller than that of the female breast, and which usually lies over the fourth intercostal space, but may lie over the fourth or fifth rib. The nipples of the two sides are rarely placed quite symmetrically. Accessory glands and accessory nipples are as common among males as females. The male breast may exhibit some evidence of temporary functional activity at birth and at puberty. Cases have been recorded of actual lactation by the male breast.

Surgical Anatomy. — The male breasts may undergo enormous hypertrophy (*gynaecomazia*). In these cases the penis is often small and the testicles may be atrophied. The breasts may be absent in the male. Disease of the male breast is not nearly so frequent as disease of the female breast. The organ may be the seat of syphilis, tuberculosis, acute or chronic mastitis, abscess or tumor. A number of cases of cancer of the male breast have been recorded.
THE SURGICAL ANATOMY OF INGUINAL HERNIA AND FEMORAL HERNIA.

Dissection (Fig. 288).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated through an aperture made at the umbilicus. An incision should be made along the middle line from a little below the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen (p. 433).—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The Superficial Layer of the Superficial Fascia or the Fascia of Camper is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart’s ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis, and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perinaeum. In the female this fascia is continued into the labia majora.

The hypogastric branch of the ilio-hypogastric nerve perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-inguinal nerve escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The superficial epigastric artery arises from the femoral about half an inch below Poupart’s ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The superficial circumflex iliac artery, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart’s ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and
the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

Fig. 1113.—Right external abdominal ring and saphenous opening in the male. (Spalteholz.)

Fig. 1114.—Right inguinal canal in the male. Second layer viewed from in front. (Spalteholz.)
The superficial external pudic (superior) artery arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are usually much larger than the arteries; they terminate in the internal saphenous vein. The superficial inguinal lymphatic glands are placed immediately beneath the integument, are of large size, and vary from ten to twenty in number (p. 793).

The Deep Layer of the Superficial Fascia, the Fascia of Scarpa or the Fascia of Cooper (p. 433) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart’s ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the base of the triangular ligament of the urethra. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends.

The Aponeurosis of the External Oblique Muscle (Fig. 1113).—This is a thin but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between
the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called Poupart’s ligament (Figs. 289, 1113, 1116, 1117, 1119, 1124, 1125). The portion which is reflected from Poupart’s ligament at the spine of the os pubis, along the pectineal line, is called Gimbernat’s ligament (Fig. 297, 340, 1113, 1124, 1125). A thin fibrous band extends from the inner end of Poupart’s ligament and Gimbernat’s ligament upward and inward behind the inner pillar of the external ring to the anterior layer of the rectus sheath. The fibres diverge as they ascend. This band is known as the triangular fascia or Colles’s fascia or the triangular ligament of Colles (Figs. 1115 and 1119).

The External or Superficial Abdominal Ring (annulus inguinalis subcutaneus) (Figs. 289 and 1113).—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the external abdominal ring. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the intercolumnar fibres, which pass across the upper angle of the ring, so as to increase its strength; and on either side by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The External Pillar, which at the same time is inferior (crus inferius), from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart’s ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The Internal or Superior Pillar (crus superior) is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interfacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, hence the great frequency of inguinal hernia in men.

The Intercolumnar Fibres (fibriæ internurales) (Fig. 1113) are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they arise from Poupart’s ligament, and they are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the intercolumnar fascia. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence, it is also called the external spermatic fascia. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring
sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downward and outward; great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (Fig. 1116). The mode of insertion of Poupart’s and Gimbernat’s ligaments into the os pubis should also be examined.

**Poupart’s Ligament** (*ligamentum inguinale* [Pouparti]) (Figs. 289, 1113, 1116, 1117, 1119, 1124, and 1125) or the crural arch is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat’s ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction; its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

**Gimbernat’s Ligament** (*ligamentum lacunare* [Gimbernati]) (Figs. 289, 297, 340, 1113, 1124, and 1125) is that portion of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the femoral sheath, forming the inner boundary of the femoral ring (Fig. 1124). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart’s ligament.

The *Triangular Fascia of the Abdomen, Colles’s Fascia* or the *Triangular Ligament of Colles* (*ligamentum inguinale reflexum* [Colleti]) (Fig. 1115, 1116, and 1119) is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the inner end of Poupart’s ligament and to Gimbernat’s ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba in the anterior layer of the sheath of the Rectus muscle.
The Ligament of Cooper.—See Fig. 297 and p. 437.

The Internal Oblique Muscle (Figs. 1114, 1115, and 1116) has been previously described (p. 437). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart’s ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis (Figs. 1116 and 1117). This tendon is inserted immediately behind the inguinal canal and external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. The conjoined tendon is sometimes divided into an outer and an inner portion, the former being called the ligament of Hesselbach (ligamentum interfoveolare) (Fig. 292), and the latter the ligament of Henle (Fig. 292). Sometimes the conjoined tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The Cremaster (Figs. 1114 and 1116) is derived from the lower margin of the Internal oblique, of which muscle it is in reality a portion. It is a thin muscular layer composed of a number of fasciculi. It arises by a thick external bundle of fibres from the upper portion of Poupart’s ligament, being connected with the Internal oblique muscle and also occasionally with the Transversalis. It arises also by a thin inner bundle of fibres from the anterior layer of the rectus sheath.

The thick bundle of origin is on the lateral surface; the thin bundle is on the medial surface of the spermatic cord. The Cremaster passes along with the spermatic cord, and descends with it through the external ring. Upon the front and sides of the cord both bundles spread out upon the vaginal tunic of the testicle and epididymis, and form a series of loops which differ in thickness and length in different subjects. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the cremasteric fascia (fascia cremasterica).

It will be observed that the Cremaster is a separated portion of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part, which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large scrotal herniae. No such muscle exists in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart’s ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inward on to the sheath of the Rectus (Fig. 1117). The deep circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.
The Transversalis Muscle (Figs. 1115 and 1117) has been previously described (p. 442). The part which is now exposed is partly muscular and partly tendinous in structure; it arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and the pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis (Figs. 1116 and 1117). The *falc aponeurotica [inguinalis]* is a collection of fibres of tendinous consistence in the inner side of the Transversalis insertion. Between the lower border of this muscle and Poupart's ligament a space is left in which is seen the transversalis fascia.

The Inguinal or Spermatic Canal (canalis inguinalis) (Figs. 1114, 1115, and 1117) contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the inguinal canal, and terminates below at the external or superficial ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the transversalis fascia with Poupart's ligament. That form of hernia in which the intestine follows the course of the spermatic cord along the inguinal canal is called *oblique inguinal hernia*.

On the posterior wall of the inguinal canal is seen the band of fibres known as the ligament of Hesselbach (ligamentum interfoveolare [Hesselbachii]) (Fig. 292). It is placed in front of the deep epigastric artery. The fibres come from the external portion of the lower fibres of the conjoined tendon (Fig. 1116) and pass
downward for a distance, some of them then passing outward and upward, some of them downward and inward to the inner surface of Poupart's ligament.

The Transversalis Fascia (Figs. 297, 1117, and 1125) is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments; external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the is pubis and pectineal line where the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the femoral sheath. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on the structures forming the infundibuliform fascia.

The Internal or Deep Abdominal Ring (annulus inguinalis abdominalis) (Figs. 297 and 1117) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, its long diameter being directed upward and downward; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference, a thin, funnel-shaped membrane, the infundibuliform fascia, is continued around the cord and testis, enclosing them in a distinct pouch (Fig. 1117). When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform fascia constitutes one of its coverings.

The Subperitoneal Areolar Tissue or the Fascia Propria of Cooper.—Between the transversalis fascia and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness and loaded with adipose tissue. Opposite the internal ring it is continued around the surface of the cord, forming a loose sheath for it.

The Deep Epigastric Artery (Figs. 292 and 1118) arises from the external iliac artery a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upward pierces the transversalis fascia and enters the sheath of the Rectus muscle by passing over the semilunar fold of Douglas. Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring and beneath the commencement of the spermatic cord. At its commencement it is crossed by the vas deferens in the male and by the round ligament in the female.

The Peritoneum (Fig. 1118), corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost, the ligament of Cloquet. This is the remains of the pouch of peritoneum which, in the foetus, precedes
the cord and testis into the scrotum, the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance, but occasionally it may be followed, as a fine cord, as far as the upper end of the tunica vaginalis. Sometimes the tube of peritoneum is closed only at intervals and presents a sacculated appearance, or a single pouch may extend along the whole length of the cord, which may be closed above, or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female fetus the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes it remains pervious even in advanced life.

In order to understand the relation of the peritoneum to inguinal hernia, it is necessary to view the anterior abdominal wall from its internal aspect, when it will be seen as shown in Fig. 1118. Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five vertical folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus. One of these is situated in the median line, and is caused by the urachus, the remnant of the allantois; it extends from the summit of the bladder to the umbilicus. The fold of peritoneum covering it is known as the fold of the urachus or the plica urachi (plica umbilicalis media). On either side of this is a prominent band, caused by the obliterated hypogastric artery, which extends from the side of the bladder obliquely upward and inward to the umbilicus. This is covered by a fold of peritoneum which is known as the

---

Fig. 1118.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)
hypogastric fold or the plica hypogastrica (plica umbilicalis lateralis). To either side of these three cords is the deep epigastric artery, which ascends obliquely upward and inward from a point midway between the symphysis pubis and the anterior superior spine of the ilium to the semilunar fold of Douglas, in front of which it disappears. It is covered by a fold of peritoneum which is known as the plica epigastrica. Between these raised folds are depressions of the peritoneum, constituting so-called fossae. The most internal, between the plica urachi and the plica hypogastrica, is known as the internal inguinal fossa (fovea supravesicalis). The middle one is situated between the plica hypogastrica and the plica epigastrica, and is termed the middle inguinal fossa (fovea inguinalis mesialis). The external one is external to the plica epigastrica, and is known as the external inguinal fossa (fovea inguinalis lateralis). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line, and the two external fossae are merged into one. In the usual condition of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossae, and through either of these a direct hernia may descend, as will be explained in the sequel (p. 1523). The whole of this space, that is to say, the space between the deep epigastric artery, the margin of the Rectus and Poupart’s ligament, is commonly known as Hesselbach’s triangle. These three depressions or fossae are situated above the level of Poupart’s ligament, and in addition to them is another below the ligament, corresponding to the position of the femoral ring, and into which a femoral hernia descends.

INGUINAL HERNIA.

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—external or oblique, and internal or direct.

External or oblique inguinal hernia, the more frequent of the two, takes the same course as the spermatic cord. It is called external from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

Oblique Inguinal Hernia.

In oblique inguinal hernia (Fig. 1118) the intestine or omentum escapes from the peritoneum at the internal ring. Before it is a pouch of peritoneum, which forms the hernial sac (Fig. 1119, A). This pouch of peritoneum is invested by the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia, which it receives as it enters the inguinal canal. In passing along the inguinal canal the hernia dislocates upward the arched fibres of the Transversalis and Internal oblique muscles, and is imperfectly surrounded by the fibres of the Cremaster muscles, the coat being completed by the cremasteric fascia. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar
OBLIQUE INGUINAL HERNIA

fascia, Cremaster muscle and fascia, infundibuliform fascia, subserous areolar tissue, and peritoneum.

This form of hernia lies in front of the vessels of the spermatic cord and seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis (Fig. 1120, A).

The seat of stricture in a strangulated oblique inguinal hernia is either at the external ring, in the inguinal canal, caused by the fibres of the Internal oblique or Transversalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the

![Fig. 1119.—Oblique inguinal hernia, showing its various coverings. (From a preparation in the Museum of the Royal College of Surgeons.]

aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the hernia passes along the inguinal canal and escapes from the external ring into the scrotum, the condition is called complete oblique inguinal or scrotal hernia (Fig. 1120, A). If the hernia does not escape from the external ring, but is retained in the inguinal canal, the condition is called incomplete inguinal hernia or bubonocele. In each of these cases the coverings which invest the intestine or omentum will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is preceded by a pouch of peritoneum, which about
the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to

near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at
two points—viz., at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

**Congenital Hernia** (Fig. 1120, B).—Where the congenital pouch of peritoneum which precedes the cord and testis in its descent remains patent throughout and is unenclosed at any point, the cavity of the tunica vaginalis communicates directly with the cavity of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

**Infantile and Encysted Hernia.**—Where the congenital pouch of peritoneum is occluded at the internal ring only, but remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the **infantile form** (Fig. 1120, C) the septum which closed the congenital sac above and the peritoneum in its immediate neighborhood yields and forms a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and the layer of the proper hernial sac. In the **encysted form** (Fig. 1120, D) yielding occurs in the same position as in the infantile form—namely, at the occluded spot in the pouch—and a sac forms which projects into and not behind the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and one of true hernial sac.

**Hernia into the Funicular Process** (Fig. 1120, E).—Where the congenital pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

**Direct Inguinal Hernia.**

In direct inguinal hernia the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space, Hesseibach's triangle, bounded externally by the deep epigastric artery, internally by the margin of the Rectus muscle, below by Poupart's ligament (Fig. 1118). The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in
front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric the projection of these arteries toward the cavity of the abdomen produces two fossae in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall—viz., an external one on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery (pp. 1519 and 1520). In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. These fossae are the \textit{inguinal fossae}. When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The \textit{seat of stricture in strangulation} in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not infrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward.\footnote{In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward; the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, the vessel would stand an equal chance of injury if the case was one of oblique inguinal hernia.—Ed. of 16th English edition.}

If the hernial protrusion passes into the inguinal canal, but does not escape
from the external abdominal ring, it forms what is called incomplete direct hernia. This form of hernia is usually of small size, and in corpulent persons is very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

**FEMORAL HERNIA.**

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon the back; a block is first placed under the pelvis, the thigh everted, and the knees slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart's ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh (Fig. 340). These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The **Superficial Fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The **internal or long saphenous vein** (Figs. 1121, 1122, and 1123) ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament (Fig. 1113). This vein receives at the saphenous opening the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins.

The **superficial external pudic artery** (superior) arises from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male and the labium in the female, anastomosing with branches of the internal pudic.

The **superficial epigastric artery** arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches
to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The superficial circumflex iliac artery, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The Superficial Veins (Fig. 1121).—The veins accompanying these superficial arteries are usually much larger than the arteries; they terminate in the internal or long saphenous vein at the saphenous opening.

The superficial inguinal lymphatic glands.—See p. 793.

The ilio-inguinal nerve arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric nerve. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The crural branch of the genito-crural nerve passes along the inner margin of the Psoas muscle, beneath Poupart's ligament, into the thigh, entering the sheath of the femoral vessels, and lying
superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The Deep Layer of the Superficial Fascia is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart’s ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart’s ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corre-

Fig. 1122.—Femoral hernia, showing fascia lata and saphenous opening.

sponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the cribriform fascia, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection (p. 513). A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.
The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The **Fascia Lata** has been already described with the muscles of the front of the thigh (p. 513). At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the **saphenous opening** (Fig. 1113). In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an **iliac portion** and a **pubic portion**.

The **iliac portion** (Fig. 1122) is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the **outer boundary** or **falciform process** or **superior cornu** (*cornu superius*) (Fig. 1122) of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the cribriform fascia, and below it is continuous with the pubic portion of the fascia lata.

The **pubic portion** of the **fascia lata** or the **pectineal fascia** (Fig. 1122) is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the
sheath of the femoral vessels, to which it is loosely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the iliop ectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From the description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture consequently exists between the two, through which the internal saphenous vein joins the femoral vein.

The Saphenous Opening (fossa ovalis) (Figs. 1113, 1121, 1122, and 1123) is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner parts of the front of the thigh, below Poupart's ligament, and is directed obliquely downward and outward. It is covered by the cribriform fascia (fascia cribrosa), a portion of the deep layer of the superficial fascia of the thigh, and which extends from the falci form margin to the pubic portion of the fascia lata or the pectineal fascia.

The outer margin of the saphenous opening is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upward, it will be seen to form a curved elongated process, the falci form process or superior cornu (Fig. 1122), which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward; this is the inferior cornu of the saphenous opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The inner boundary of the opening (Figs. 1113 and 1122) is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb and inverting it; hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its femoral process, should now be removed by detaching it from the lower margin of Poupart's ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart's ligament (Fig. 1123).

Poupart's Ligament (ligamentum inguinale [Pouparti]) (Figs. 289, 1113, 1116, 1117, 1119, 1122, 1123, 1124, and 1125) is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming Gimbernet's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between Poupart's ligament and the innominate bone is filled in by the parts which descend from the abdomen into the thigh (Figs. 297, 340, and 1124). The outer half of the space (lacuna musculorum) is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half of the space (lacuna vasorum) is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath,
which is occupied merely by a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral ring, through which the gut descends in femoral hernia. The part of Poupart's ligament in front of the femoral or crural ring is called the superficial crural arch.

Gimbernat's Ligament (ligamentum lacunare [Gimbernati]) (Figs. 297, 340, 1113, 1124, an.1125) is that part of the aponeurosis of the External oblique muscle which is reflected backward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the femoral sheath. Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

Femoral Sheath (Fig.1124).—The femoral or crural sheath is a continuation downward of the fasciae that line the abdomen, the transversalis fascia passing down in front of the femoral vessels, and the iliac fascia descending behind them; these fasciae are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the femoral or crural canal (Fig. 1113). The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath
is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed (Fig. 1113), the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral or crural canal (Fig. 1113), through which the intestine descends in femoral hernia.

**Deep Crural Arch.**—Passing across the front of the femoral sheath on the abdominal side of Poupart’s ligament, and closely connected with it, is a thickened band of fibres of the transversalis fascia, called the deep crural arch. It is apparently a thickening of the transversalis fascia, joining externally to the centre of Poupart’s ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting. The superficial crural arch is the portion of Poupart’s ligament in front of the femoral ring.

The **Femoral or Crural Canal** (canalis femoralis) (Figs. 297, 340, and 1113) is the narrow interval between the femoral vein and the inner wall of the femoral sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from the femoral ring to the upper part of the saphenous opening.

Its **anterior wall** is very narrow, and formed by a continuation downward of the transversalis fascia, under Poupart’s ligament, covered by the falciform process of the fascia lata.

Its **posterior wall** is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its **outer wall** is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its **inner wall** is formed by the junction of the processes of the transversalis and iliac fasciae, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat’s ligament.

This canal has two orifices—an upper one, the femoral or crural ring, closed by the septum crurale; and a lower one, the saphenous opening, closed by the cribriform fascia.

The **femoral or crural ring** (annulus femoralis) (Figs. 1113, 1124, and 1125) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart’s ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat’s ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

**Position of Parts around the Ring.**—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the
femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The femoral vein lies on the outer side of the ring.

The **deep epigastric artery** in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The **communicating branch** between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind (Fig. 1125). It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The **obturator artery** (p. 688), when it arises by a common trunk with the deep epigastric (p. 689), which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In most cases it descends on the inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (Fig. 427 A, p. 689). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen; it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (Fig. 427 B, p. 689).

**The Crural Septum or Septum Crurale** (*septum femorale musculus*) (Fig. 297).—

The femoral ring is closed by a thin process of transversalis fascia containing fat and called, by J. Cloquet, the **septum crurale**. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland (Fig. 1125), by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.
The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral canal and its orifices are rendered tense from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The subperitoneal areolar tissue is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the femoral ring, the small interval on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. Here there is no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall; hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine passes through the femoral ring, a pouch of peritoneum lies before it, which forms what is called the hernial sac; it is covered by the subserous areolar tissue, receives an investment from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the hernia is consequently directed forward, pushing before it the cruriform fascia, and then curves upward on to the falciiform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Complete Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cruriform fascia, superficial fascia, and integument.1

1Sir Astley Cooper has described an investment for femoral hernia, under the name of "fascia propria," lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text "subserous areolar tissue," the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.—Ed. of 15th English edition.
Varieties of Femoral Hernia.—If the hernia descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, the condition is called incomplete femoral hernia. The small size of the protrusion in this form of hernia, which is due to the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia, named from without inward, are as follows: the integument, superficial fascia, iliac portion of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernia protrudes through the saphenous opening and directs itself forward and upward, it forms a complete femoral hernia, the coverings of which have been given (p. 1533). Occasionally the hernial sac descends on the iliac side of the femoral vessels or in front of these vessels, or even sometimes behind them.

The seat of stricture in a strangulated femoral hernia varies; it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat’s ligament, or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in an inward direction, or upward and inward, and the extent of the necessary cut in the majority of cases is about two or three lines. By these means all vessels or other structures of importance in relation with the neck of the hernial sac will be avoided.
Surgical Anatomy of the Perineum.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 1126, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The Perineum corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the os pubis and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thigh. A line drawn transversely between the anterior parts of the tuberosities of the ischium, on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the perineum proper or genito-urinary region. The posterior portion contains the termination of the rectum, and is called the ischio-rectal or anal region.

Ischio-rectal region.

The ischio-rectal region contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium; this is called the ischio-rectal fossa.

The ischio-rectal region presents in the middle line the aperture of the anus; around this orifice the integument is thrown into numerous folds, which are obliterated on distention of the anus. The integument is of a dark color, continuous with the mucous membrane of the rectum, and is provided with numerous

Fig. 1126.—Dissection of perineum and ischio-rectal region.
fistulae, which occasionally inflame and suppurate, and may be mistaken for fistulae. The veins around the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish color, covered partly by mucous membrane and partly by the integument. These tumors constitute the disease called external piles.

Dissection (Fig. 1126).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it around the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

The Superficial Fascia is exposed on the removal of the skin; it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three branches of the perforating cutaneous nerve; these turn around the inferior border of the Gluteus maximus and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Levator ani.

These muscles have been already described (p. 449).

The Ischio-rectal Fossa (fossa ischiorectalis) (Figs. 300 and 304) is situated between the end of the rectum and the ischial tuberosity. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its apex, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, internally, by the Sphincter ani, Levator ani, and Coccygeus muscles; externally, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; in front, it is limited by the line of junction of the superficial fascia with the base of the triangular ligament; and behind, by the margin of the Gluteus maximus muscle and the great sacro-scatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and the two divisions of the nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath, the fascial canal or canal of Alcock (Figs. 304 and 1131), formed by the obturator fascia, the pudic nerve lying below the artery and the dorsal nerve of the penis above it. Crossing the space transversely, about its centre are the inferior hemorrhoidal vessels and nerves, which are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hemorrhage when divided in the operation of lithotomy or in that for fistula in ano. At the back part of this space, near the coccyx, may be seen a branch of the fourth sacral nerve, and at the forepart of the space the superficial perineal vessels and nerves can be seen for a short distance.
THE PERINEUM PROPER IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the anterior parts of the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perineum is subdivided by the median raphé into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perineum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the raphé, continuous in front with the raphé of the scrotum. The skin of the raphé is adherent to the deep layer of the superficial fascia.

Upon removing the skin and the superficial layer of the superficial fascia, in the manner shown in Fig. 1126, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the deep layer of the superficial fascia or fascia of Cocles (fascia superficialis perinaei). It has already been described (p. 456). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the fascia of the penis and the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversalis perinaei muscles to join the base of the triangular ligament.

It is between this layer of fascia and the triangular ligament of the urethra that extravasation of urine most frequently takes place in cases of rupture of the urethra. The triangular ligament of the urethra (p. 450) is attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, because the two layers are continuous with each other around the Transversi perinaei muscles: it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis because the opening into this cavity is closed by the triangular ligament, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and then on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed (Fig. 1127), a space is exposed, between this fascia and the triangular ligament, in which are contained the superficial perineal vessels and nerves and some of the muscles connected with the penis and urethra—viz., in the middle line, the Accelerator urinæ; on each side, the Erector penis; and behind, the transversus perinaei; together with the crura of the corpora cavernosa and the bulb of the corpus spongiosum. Here also is seen the central tendinous point of the perineum. This is a fibrous point in the middle line of the perineum between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached—viz., the External sphincter ani, the Accelerator urinæ, and the two Transversi perinaei
muscles; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Accelerator urinae, the Erector penis, and the Superficial transversus perinaei muscles have been already described (p. 457). They form a triangular space (Fig. 1127), bounded, internally, by the Accelerator urinae; externally, by the Erector penis; and behind, by the Transversus perinaei. The floor of this space is formed by the triangular ligament of the urethra; and running forward in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space, on the Transversus perinaei muscle.

The Accelerator urinae and Erector penis should now be removed, when the triangular ligament of the urethra will be exposed, stretching across the front of the outlet of the pelvis. The urethra is seen perforating its centre, just behind the bulb; and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

The Triangular Ligament or the Deep Perineal Fascia (trigonum urogenitale or diaphragma urogenitale) (Figs. 309, 310, and 1128), which has been already described (p. 459), consists of two layers, the inferior anterior or superficial layer (fascia trigoni urogenitalis inferior) of which is now exposed. It is united to the superior or deep layer behind, but is separated in front by a subfascial space in which are contained certain structures.

The inferior layer of the triangular ligament (Figs. 305 and 310) consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side of the urethral opening by the ducts of Cowper’s glands and by the arteries of the bulb; in front, and external to this, by the artery
of the corpus cavernosum, immediately before this vessel enters the crus penis. Near its apex the ligament is perforated by the termination of the pudic artery and by the dorsal nerve of the penis. The apex of the triangular ligament is known as the transverse perineal ligament. The crura penis are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and passing forward and inward, joining to form the body of the penis. In the middle line the bulb and corpus spongiosum are exposed by the removal of the Accelerator urinae muscle.

If the inferior layer of the triangular ligament is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the ligament: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethrae muscle; Cowper's glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

The superior, deep, or posterior layer of the triangular ligament or deep perineal fascia (fascia trigoni urogenitalis superior) (Fig. 305) is derived from the obturator fascia, and is continuous with it along the pubic arch. Behind, it joins with the inferior layer of the triangular ligament, and is continuous with the anal fascia. Above it is the prostate gland (Fig. 1129), supported by the anterior fibres of the Levator ani, which act as a sling for the gland and form the Levator prostaticae muscle. The superior layer of the triangular ligament is continuous around the anterior free edge of this muscle with the layer of recto-vesical fascia covering the prostate gland. The superior layer of the triangular ligament is perforated by the urethra. Between the two layers of the triangular ligament are situated the membranous part of the urethra, enveloped by the Compressor urethrae muscle (Fig. 309); the ducts of Cowper's glands; the arteries to the bulb; the pudic vessels and the dorsal nerve of the penis. The membranous part of the urethra is about three-quarters of an inch in length, and passes downward and
forward behind the symphysis pubis, from which it is distant about an inch. It is the narrowest part of the tube, and is enveloped, as has already been stated, by the Compressor urethrae muscle.

The Compressor urethrae has already been described (p. 460). In addition to this muscle, and immediately beneath it, circular muscular fibres surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands (Figs. 303, 1128, and 1129) are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

The Pudic Vessels (Figs. 1128 and 1129) and Dorsal Nerve of the Penis (Fig. 310) are placed along the inner margin of the pubic arch (p. 1536).

The Artery of the Bulb (Figs. 1128 and 1129, and p. 691) passes transversely inward, from the internal pudic artery (p. 689) along the base of the triangular ligament, between its two layers, accompanied by a branch of the pudic nerve. If the superior layer of the triangular ligament is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani muscle, covered by the anal fascia, is brought fully into view (Figs. 302, 303, and 304). This muscle, with the triangular ligament in front and the Coccygeus and Pyriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (p. 451).

Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous point of the perineum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculae seminales, and the vasa deferentia will be exposed.

The Prostate Gland (p. 1129) is a pale, firm, glandular body which is placed immediately below the neck of the bladder, around the commencement of the
urethra. It is placed in the pelvic cavity, behind the lower part of the symphysis pubis, above the superior layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed upward toward the neck of the bladder. Its apex is directed downward to the deeper layer of the triangular ligament, which it touches.

Its posterior surface is smooth, marked by a slight longitudinal furrow, and rests on the second part of the rectum, to which it is connected by areolar tissue. Its anterior surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy. The prostate has a sheath derived from the recto-vesical fascia (p. 1449).

Above the prostate a small triangular portion of the bladder is seen (Fig. 1129), bounded, in front and below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; on each side, by the seminal vesicle and the vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts. This portion of the bladder was consequently selected in the old days for the performance of the now obsolete operation of tapping the bladder.

**Surgical Anatomy. Median Lithotomy.—** As the incision is in the raphé, the hemorrhage is trivial, and there is but slight risk of injuring the pelvic fascia. But the operation gives little room for manipulation and is inadmissible in children, because in them dilatation of the wound may tear the bladder loose from the urethra. A risk of median lithotomy is division of the artery of the bulb.

In median lithotomy a grooved staff is introduced, the groove being median. The knife is introduced in the mid-line, just in front of the anal margin, and hits the staff near the apex of the prostate; the entire length of the membranous urethra is cut as the instrument is withdrawn.

**Parts Divided.—**Skin; superficial fascia, sphincter ani muscle, central tendon of the perineum, inferior leaf of the triangular ligament, membranous urethra, and the Compressor urethrae muscle.

**Lateral Lithotomy.—**The operation is performed on the left side of the perineum, as this is most convenient for the right hand of the operator. A grooved staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (i.e., in an ordinary adult perineum about an inch and a half in front of the anus) a little on the left side of the raphé, and is carried obliquely backward and outward to midway between the anus and tuberosity of the left ischium. The incision divides the integument and superficial fascia, the inferior hemorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering the staff are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may need to be notched before the forceps is introduced; the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

**Parts Divided in the Operation.—** The various structures divided in this operation are as follows: the integument, superficial fascia, inferior hemorrhoidal vessels and nerves, and prob-
ably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinæ muscle, the Transversus perinæi muscle and artery, the triangular ligament, the anterior fibres of the Levator ani muscle, part of the Compressor urinæ muscle, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perineum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the internal pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, only the anterior part of the prostate is divided, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder before the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perineum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischiæ, is liable in its passage forward to the bulb to be wounded in the operation of lithotomy. The accessory pudic may be divided near the posterior border of the prostate gland, if this gland is completely cut across; and if the prostatic veins are of large size, and give rise, when divided, to troublesome hemorrhage. In men advanced in years the prostatic veins are very apt to be enlarged.

Extravasation of Urine.—Extravasation most commonly occurs from urethral rupture, between Colles’s fascia and the triangular ligament of the urethra (extravasation in front of the triangular ligament). The adherence of these two fascial layers posteriorly prevents the urine from passing backward. The urine cannot find a way laterally, because both layers on each side are attached to the rami of the pubes and ischiæ. It cannot reach the pelvis, because the triangular ligament bars the way. It can only go forward if the two fascial layers remain intact, and consequently the urine passes into the areolar tissue of the scrotum beneath the superficial fascia of the penis and of the anterior abdominal wall.

Pus and blood would pursue the same course in this space. Effusions in this space causes much pain, because the space contains the three long scrotal nerves.

In rupture of the urethra between the two layers of the triangular ligament, the urine remains in this situation as long as fascia remains intact. If suppuration occurs, destruction of fascia liberates the urine.

In rupture behind the superior layer of the triangular ligament (extravasation back of the triangular ligament), the urine passes into the ischio-rectal fossa and upward and backward into the pelvis.

THE FEMALE PERINÆUM.

The female perineum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The Superficial Fascia, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is, like it, attached to the ischio-pubic rami, and in front is continued forward through the labia majora to the inguinal region. It is of less extent than in the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perineum, which have already been described (p. 461), are exposed (Figs. 311 and 1130). The Sphincter vaginae, corresponding to the Accelerator urinæ in the male, consists of an atten-
uated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphe, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect from the erecter penis, and the Transversus perinaei is similar to the muscle of the same name in the male.

The triangular ligament (Fig. 1130) is not strongly marked as in the male. It transmits the urethra and the tube of the vagina.

The Compressor Urethrae corresponds with the Compressor urethrae in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perinæum.

Fig. 1130.—The female perinæum after removal of the skin and superficial fascia. (Bardeleben.)

The distribution of the internal pudic artery is the same as in the male (p.1540), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the bulbi vestibuli and partes intermediales.

The Perineal Body fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and
vagina on what is called the **perineum**. Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perineum are inserted.

**The Pelvic Fascia** (*fascia pelvis*) (Figs. 304 and 1131).—The pelvic fascia strengthens the floor of the pelvis, fastens pelvic structures together, and supports the nerves, blood-vessels, and lymphatics. It is connected above with the transversalis fascia and the iliac fascia. It is at first a thin membrane and covers the inner surface of the pelvis, being attached to the brim for a short distance at the side of the cavity and to the inner surface of the bone around the attachment of the Obturator internus. At the posterior portion of this muscle it is continued backward as a very thin membrane in front of the Pyriformis muscle to the front of the sacrum. In front, as it descends, it gives off the **parietal layer of the pelvic fascia**, which continues as the **obturator fascia**. It then becomes thicker and covers the inner and upper surface of the Diaphragm of the pelvis as far as the **white line** (*arcus tendineus fasciae pelvis*). The portion covering the superior and upper surface of the pelvic Diaphragm is the inner sheath of the Levator ani muscle and is called the **visceral layer of the pelvic fascia** or the **recto-vesical fascia** (*fascia diaphragmaticis pelvis superior*). The white line is a rough band of fascial thickening, seen in the pelvic fascia of each side. It indicates the line of separation between the pelvic cavity and the ischio-rectal fossa. It passes from the lower
portion of the symphysis pubis outward and backward to the spine of the ischium. It makes the attachment of the Levator ani muscle to the pelvic fascia. At the white line the chief mass of the pelvic fascia passes upon the pelvic viscera and is known as the fascia endo-pelvica. It covers portions of the vagina, rectum, and urinary bladder, becomes thinner and thinner, and is gradually lost. Other bands of fascia begin at the white line, descend on the inner surface of the recto-vesical fascia, and in the male pass to the tip of the prostate and become the prostatic fascia. Between the anterior ends of the two white lines the level of the fascia is lower, and it forms a fossa, bounded on the sides in the male by the pubo-prostatic ligaments (ligamenta puboprostatica lateralia), and in the female by the pubo-vesical ligaments (ligamenta pubovesicalia lateralia). These ligaments are called the lateral true ligaments of the bladder. In the base of this fossa in the male runs the anterior true ligament of the bladder or the pubo-prostatic ligament (ligamentum puboprostaticum medium), and in the female the anterior true vesical ligament (ligamentum pubovesicae medium). These ligaments arise from the lowest portion of the symphysis and pass to the urinary bladder and prostate in the male, and urinary bladder and urethra in the female (Spalteholz). The outer surface of the pelvic Diaphragm is covered by the anal fascia or the ischio-rectal fascia (fascia diaphragmaticis pelvis inferior). It is the lower or outer sheath of the Levator ani muscle, and is derived from the obturator fascia. The space between the obturator fascia and the anal fascia is pyramidal and is called the ischio-rectal fossa (fossa ischiorectalis).

The pelvic fascia does not completely invest the bladder, although the neck and lateral walls lie upon the Levator ani muscles, and the lateral true ligaments and the anterior ligament ascend upon the sides and front of the bladder and are lost upon the fibrous coat of that viscus. The sides and anterior wall have a fascial investment. The sheath of the prostate has already been discussed (p. 1449). It is
continuous with the recto-vesical fascia and the anterior true ligament of the bladder.

The pelvic fascia is composed, according to Hughes, of: 1. The fibrous capsules of the pelvic viscera. 2. The sheaths of the Levator ani and Coecygei muscles (recto-vesical and anal fasciae). 3. The sheath of the Obturator internus (obturator fascia). 4. Sheath of the Compressor urethrae muscle (the triangular ligament). 5. The sheath of the pelvic aspect of the Pyriformis muscle. The sacral plexus is outside this sheath, the internal iliac vessels inside of it. As previously stated, the pelvic fascia gives off the obturator fascia and the recto-vesical fascia.

The Obturator Fascia (fascia obturatoria) descends and covers the Obturator internus muscle. It is a direct continuation of the parietal pelvic fascia below the white line above mentioned, and is attached to the pelvic arch, the ischial tuberosities, and to the margin of the great sacro-scatic ligaments. This fascia forms a canal for the pudic vessels and nerve in their passage forward to the perineum, and gives off a thin membrane which covers the perineal aspect of the Levator ani muscle, and is called the anal or ischio-rectal fascia. It forms the inner boundary of the ischio-rectal fossa. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the deep layer of the triangular ligament.

The Recto-vesical Fascia or the Visceral Layer of the Pelvic Fascia (fascia endopelvea) descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued, on each side of the middle line, to the upper surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued on to the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the seminal vesicle, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected around the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia, the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the ischio-rectal or anal fascia. In the female the vagina perforates the recto-vesical fascia and receives a prolongation from it.

1 A Manual of Practical Anatomy. By Prof. Alfred W. Hughes; edited and completed by Dr. Arthur Keith.
CHRONOLOGICAL TABLE OF THE DEVELOPMENT OF THE FETUS.

(From Beaunis and Bouchard.)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes imbedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove, and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral disks, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The branchial arches are formed. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fosse, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germ of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commissure of the interauricular septum, the salivary glands, the spleen, and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

1 [Eternod (Anat. Anzeiger, Band xv., 1898) described an ovum which he reconstructed. It had a precise history, from which he concluded that it must have belonged to the end of the second or the beginning of the third week. Including the villi it measured 10 × 8.2 × 8 mm. It was flattened on its embryonal side, and the embryo measured 1.3 mm. The amnion was completely formed and the allantois existed as a long canal. The vitelline circulation was established and the villi of the chorion were beginning to be vascularized. The blastopore still opened into the amniotic cavity, with the primitive groove behind it and the rudimentary groove in front. The notochord was closing in and all three layers of the blastoderm were distinct, except around the blastopore, where they formed an undivided mass.—Ed. of 15th English edition.]
Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebrae, of the frontal, vomer, and malar bones of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the fetal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture in divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone and ossification of the germs of the teeth take place. The germs of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner’s glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillae of the skin, the sebaceous glands, and Peyer’s patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel’s cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigramina are apparent. The papillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebrae, can be seen.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinate bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.

ethmo-frontal, 130
-ethmoidal, 130
frontal, 79, 127
fronto-malar, 128
-parietal, 127
-ethmoidal, 128, 130
intermaxillary, 130
internasal, 139
interparietal, 127
lambdoid, 75, 78, 128
masto-occipital, 75, 128
-parietal, 128
metopic, 83, 127
naso-maxillary, 130
occipito-parietal, 128
petro-occipital, 75, 128, 133
-ethmoidal, 128, 136
-squamous, 88
sagittal, 78, 127
sphenoparietal, 128
squamo-parietal, 128
-squamosal, 128
squamous, 83, 128
transverse, 128

Sweat-glands, 1190
Sylvian point, 866
vein, superficial, 735
Sylvius, aqueduct of, 912
 fissure of, 866, 884
Symington, ano-coccygeal body of, 1316
Sympathetic nerve, 1066
ganglion of, 1078
plexuses of, 1080
structure of, 1068
Synapsis, 264, 267
of jaw, 122
sacro-coccygeal, 66
Synarthrosis, 264
Synchondrosis, 264
Syndeos-odontoid joint, 274
Synodesmosis, 265
Synovial bursa, 263
ligaments, 262
membranes, 262
articular, 262
bursal, 263
of flexor tendon at wrist, 492
surgical anatomy of, 492
vaginal, 263. See also Individual joints.
sheaths, 263
villi, 262

Systemic arteries, 583
veins, 724

TABLES of skull, 33
Tabular portion of occipital bone, 71
Tactile corpuscle, 827
Talnia fornicis, 896, 898
hippocampi, 896
pontes, 883
semicircularis, 891, 894
thalamus, 904
Tapetum of choroid, 1114
trabecula, 1127
nigra, 1127
Tarsal arch, 623
artery, 715
bones, development of, 233
glands, 1139
joint, surgical anatomy of, 356
ligament, external, 370
internal, 370

Tarsal plates of eyelid, 1139
Tarsometatarsal articulations, 357
Tarsus, 242
articulations of, 352
surface form of, 253
surgical anatomy of, 256
synovial membrane of, 352
Taste-buds, 1090
Teeth, 1195
arrangement of, 1198
auditory, 1173
bicuspids, 1138
canine, 1197
cementum of, 1204
coronal substance of, 1204
deciduous, 1196
development of, 1204
e name of, 1203
eruption of, 1208
eye, 1107
general characters of, 1195
grinders, 1198
incisors, 1196
ivory of, 1202
milk, 1198
molar, 1198
permanent, 1196
superadded, 1208
premolars, 1198
roots of, 1196
solid portion of, 1201
stomach, 1197
structure of, 1200
surfaces of, 1195
temporary, 1196
Tegmen tympani, 87
Tegmental region, subthalamic, 885
Tegmentum, 908
of crus cerebri, 885
fibres of, 908
nucleus of, red, 908
Tela choroidea inferior, 856, 943
superior, 854, 901
subependyma, 1180
Temporal artery, 611
anterior, 611, 640
from internal maxillary, 614
middle, 611
posterior, 611, 640
surgical anatomy of, 612
bone, 83
articulations of, 92
attachment of muscles to, 92
development of, 91
mastoid portion of, 85
petrous portion of, 88, 136
squamosal portion of, 83
convolution, 877
crest, 76, 80, 84
dioploe vein, 734
fascia, 381
fossa, 76, 137
horn of lateral ventricle, 890
lines, 76, 80
lobe, 885
muscle, 382
nerves, from auriculo-temporal, 1038
deep, 1037
from facial, 1032, 1049
ridges, 76, 80
sulci, 868
sulci, first, 877
fourth, 875
inferior, 870
second, 877
third, 878
veins, 727
